Amyloid β -protein, A β , is normally produced in brain and is cleared by unknown mechanisms. In Alzheimer's disease (AD), A β accumulates in plaque-like deposits and is implicated genetically in neurodegeneration. Here we investigate mechanisms for A β degradation and A β toxicity *in vivo*, focusing on the effects of A β 40, which is the peptide that accumulates in apolipoprotein E4-associated AD. Chronic intraventricular infusion of A β 40 into rat brain resulted in limited deposition and toxicity. Coinfusion of A β 40 with the cysteine protease inhibitor leupeptin resulted in increased extracellular and intracellular A β immunoreactivity. Analysis of gliosis and TUNEL in neuron layers of the frontal and entorhinal cortex suggested that leupeptin exacerbated A β 40 toxicity. This was supported further by the neuronal staining of cathepsin B in endosomes or lysosomes, colocalizing with intracellular A β immunoreactivity in pyknotic cells. Leupeptin plus A β 40 caused limited but significant neu-

ronal phospho-tau immunostaining in the entorhinal cortex. Intriguingly, A β 40 plus leupeptin induced intracellular accumulation of the more toxic A β , A β 42, in a small group of septal neurons. Leupeptin infusion previously has been reported to interfere with lysosomal proteolysis and to result in the accumulation of lipofuscin, dystrophic neurites, tau- and ubiquitin-positive inclusions, and structures resembling paired helical filaments. Coinfusion of A β 40 with the serine protease inhibitor aprotinin also increased diffuse extracellular deposition but reduced astrogliosis and TUNEL and was not associated with intracellular A β staining. Collectively, these data suggest that an age or Alzheimer's-related defect in lysosomal/endosomal function could promote A β deposition and DNA fragmentation in neurons and glia similar to that found in Alzheimer's disease.

Key words: Alzheimer's disease; A β ; lysosome; cathepsins; leupeptin; aprotinin; neurotoxicity; *in vivo*; rat

Alzheimer's disease (AD) is characterized by the age-related accumulation of deposits of a 40 or 42 amino acid peptide, amyloid β -protein (A β). This peptide is produced and secreted normally by cultured cells (Haass et al., 1992; Shoji et al., 1992) and is found in normal CSF (Seubert et al., 1992). Familial AD caused by genetic mutations is associated either with increased A β production of the more amyloidogenic peptide, A β 1–42 (Scheuner et al., 1996; Selkoe, 1997), or, as with apolipoprotein E4 (ApoE4), with increased accumulation of A β 40 (Ishii et al., 1997; Mann et al., 1997). However, the majority of AD cases is not early onset and does not appear to be linked to mutations that directly increase A β . An alternative mechanism for the late-onset cases could be an age-related decline in the removal or degradation rate for A β . These studies sought to investigate this mechanism *in vivo*.

There are two obvious pathways for the degradation of secreted A β : degradation by extracellular proteases or reuptake into the endosomal/lysosomal system, followed by intracellular

degradation. Others have shown that extracellular proteases, including trypsin or trypsin-like serine proteases and metalloproteases, readily degrade A β secreted by cultured cell lines (Naidu et al., 1995; Backstrom et al., 1996; Qiu et al., 1997). Further, on the basis of N-terminal modifications in deposited peptides, aminopeptidases also may initiate A β degradation (Kuda et al., 1997).

A β degradation also can occur intracellularly in endosomes and lysosomes of cultured fibroblasts (Palmer et al., 1989; Knauer et al., 1992), microglia (Shaffer et al., 1995; Ard et al., 1996), and a human neuroblastoma cell line (Ida et al., 1996). A β aggregates, notably from A β 1–42, can accumulate intracellularly in the endosomal/lysosomal system and mediate toxicity (Yang et al., 1995; Burdick et al., 1997). Most *in vitro* A β toxicity data focus on the toxic effects of fibrils that generally are believed to act at the cell surface. Lipoproteins may be responsible for the delivery of A β to the endosomal/lysosomal system for degradation (Narita et al., 1997). A sizable pool of A β rides on carrier proteins, notably lipoproteins containing ApoE, a known mediator of AD risk, and ApoJ (Ghisso et al., 1993; Biere et al., 1996; Koudinov et al., 1996). Rat A β infusion paradigms suggest that microglia or related monocytes actively take up and accumulate A β in rodent brain (Frautschy et al., 1992, 1996). When microglia cultures are treated with soluble A β and leupeptin, which inhibits its degradation, the A β readily accumulates in lysosomes period (Ard et al., 1996). Collectively, these data suggest that compromising lysosomal function *in vivo* would lead to a significant accumulation of A β .

Although both extracellular and endosomal/lysosomal A β degradation pathways are active in various *in vitro* systems and could be active in the brain, we sought to test whether specific degradation pathways were active in the brain by using a rat A β infusion paradigm. A β 40 was chosen because ApoE4 dosage, a major genetic risk factor for AD, appears to correlate positively with A β 40 accumulation (Ishii et al., 1997; Mann et al., 1997). In recognition of the possibility that the inhibition of A β degradation might promote toxicity, we also evaluated toxicity and glial responses.

MATERIALS AND METHODS

Surgeries and A β infusion. In this study 4-month-old Sprague Dawley female rats (200–250 gm body weight) were used. Surgical and animal care procedures were performed with strict adherence to the *Guide for the Care and Use of Laboratory Animals* (National Institutes of Health Publication number 86-23, Bethesda, MD). Rats were quarantined for 1 week after arrival at the housing facility to avoid specific contagious pathogens. The rats were kept on a 12 hr light/dark cycle and given food and water *ad libitum*.

Surgery. After quarantine, rats were allowed 1 additional week to adapt to their new environment. After anesthesia (1.875 mg/kg acepromazine, 37.5 mg/kg ketamine, and 1.9 mg/kg xylazine, i.m.), stainless steel brain catheters (Alza, Palo Alto, CA) were implanted with the use of a David Kopf stereotaxic instrument [at coordinates -0.8 mm anteroposterior (AP), -1.4 mm mediolateral (ML) to bregma, and -3.5 mm dorsoventral (DV) to cranium] and were attached with polyethylene tubing to subcutaneous miniosmotic pumps (Alzet 2004, Alza) under the dorsal neck, as described previously (Frautschy et al., 1996). The pump contents, released over 4 weeks, contained one of five treatments: (1) vehicle (4 mM HEPES, pH 8.0), (2) A β 40, (3) aprotinin (Sigma, St. Louis, MO), (4) leupeptin (Sigma), (5) A β 40 coinjected with aprotinin, or (6) A β 40 coinjected with leupeptin. Over the 1 month period each rat was infused with a total of 20 μ g (5 nmol) of A β 40 and/or 2 mg of protease inhibitors (31 μ mol of aprotinin and 4.2 μ mol of leupeptin).

Immunocytochemistry. After infusion the rats were anesthetized and perfused with 4% paraformaldehyde, as previously described (Frautschy et al., 1996). Brains were removed and cut rostrally into blocks that included the region of the cannula and 3 mm posterior. Blocks were paraffin-embedded, sectioned at 8 μ m, mounted, and processed for immunohistochemistry, using standard techniques (Mak et al., 1994). For A β antibodies, a 10 min period of 70% formic acid pretreatment was used (Yang et al., 1994). Sections stained for phosphotyrosine (PT; Sigma) (Korematu et al., 1994) or glial fibrillary acidic protein (GFAP; Sigma) were pretreated with a citrate buffer (antigen unveiling system; Vector Laboratories, Burlingame, CA) in a pressure cooker for 1 min after boiling, which facilitated consistent and homogenous labeling throughout the sections. Cathepsin B (graciously supplied by Dr. R. A. Nixon, Nathan Kline Institute, New York University Medical Center, Orange-

burg, NY) was diluted at 1:200. Immunostaining for cathepsin B was improved greatly by the pretreatment of sections with Tris-buffered saline (TBS) in the microwave until the buffer boiled for 2 sec, followed by 10 min of incubation or until the buffer temperature decreased from 90 to 70°C. After hydrogen peroxide quenching, blocking with 5% normal serum dissolved in PBS plus 0.3% Triton X-100, and incubation with primary antibodies overnight at 4°C, the sections were labeled with secondary biotinylated antibodies and treated with the Vector ELITE ABC kit or ABC-AP kit. We used the peroxidase substrate metal-enhanced diaminobenzidine (DAB; Pierce, Rockford, IL) (Yang et al., 1994) and the alkaline phosphatase substrate Vector blue for double staining. Some sections were counterstained with contrast green (Vector Laboratories) to locate nuclei. Congo red and thioflavin S staining was performed as previously described (Hsiao et al., 1996). Adjacent sections from each treatment were stained with antibody preabsorbed with A β 42 peptide to determine the specificity of the immunostaining (Frautschy et al., 1996). 10G4 monoclonal to the 1–13 region of native human A β 40 (Yang et al., 1994) was used for the quantitative analysis of deposition. Additional sections were labeled with 4G8 monoclonal to A β 17–24 (Senetek, Maryland Heights, MO) and Saido42, an end-specific antibody against A β 42 (Saido et al., 1995).

Terminal deoxynucleotidyl transferase-mediated dUTP-biotin nick end labeling (TUNEL). The “Apoptag” kit (Oncor, Gaithersburg, MD) was used for *in situ* end labeling of the DNA fragments as per the manufacturer’s instructions, with 30 min of proteinase K room temperature pretreatment and DAB as the peroxidase substrate. Then some TUNEL-stained sections were stained for choline acetyltransferase with ChAT goat IgG antibody (Chemicon, Temecula, CA) diluted 1:100 and were incubated for 1 hr at 37°C. Biotinylated anti-goat secondary antibody (1:1000; Vector Laboratories) was added, followed by ABC-alkaline phosphatase (1:100) and Vector blue alkaline phosphatase substrate.

Image and statistical analysis. All histological and immunohistochemical images were acquired from an Olympus Vanox-T (model AHB) microscope with an Optronix Engineering LX-450A charge-coupled device video camera system. Then the video signal was routed into a Power Center 120 Macintosh-compatible microcomputer via a Scion Corporation AG-5 averaging frame grabber. Once digitized, the images were analyzed with National Institutes of Health Image public domain software (developed at National Institutes of Health and available on the internet at <http://rsb.info.nih.gov/nih-image/>). Custom Pascal macro subroutines were written and used to calculate area, particle size, and density of microglial, astrocytic, or TUNEL-positive cells. Each capture was exposed to the same computer subroutine and density slice thresholding. The same slides were analyzed single-blind by two different microscopists to ensure that trends were independent of individual bias. The “cell density analysis” macro was run at 200 $\times$ optical magnification for the accurate resolution of cells. The parameters measured were percentage area immunostained, number of cells per square millimeter, and average size of cell. Layers II–III of the frontal cortex and layer II of the piriform cortex were analyzed as an average of four fields per rat. The “plaque analysis macro”, run at 100 $\times$ optical magnification, allowed for

Figure 1. A β immunoreactivity (A β -ir) with 10G4 monoclonal to A β in hippocampus (*A*) and frontal cortex (*B*) of rats coinjected intraventricularly with leupeptin plus A β 40 for 1 month. The inset shows a higher magnification of a cortical plaque centered on a darkly stained cell, possibly a neuron. *C*, Illustrated is punctate intracellular 10G4 A β immunoreactivity in the entorhinal cortex, which was widespread in leupeptin plus A β -treated rats. Fragmented cell processes emanated from A β -containing cells (thick arrows). A β -ir cells were prevalent in leupeptin plus A β -treated rats (*leu*+A β ; *D*) but were rare in rats infused with leupeptin alone (*leu*; *E*, thin arrows). Scale bars: *A–E*, 100 μ m; inset in *B*, 25 μ m.

Figure 2. Confocal microscopy of A β and end-specific Saido42 staining in the septum of a rat treated with leupeptin plus A β 40. *A*, The arrowhead indicates colocalization of 10G4 and Saido42 immunoreactivity (yellow) in a large cell of neuron size. Arrows indicate those cell compartments in which 10G4 staining is apparent (rhodamine) without Saido42 staining (FITC). The inset shows an extracellular plaque in the same region that stains with 10G4, but not with Saido42. *B*, Shown is the same field as *A* with the rhodamine (10G4) channel alone. *C*, Demonstrated is the same field as *A* with the FITC channel alone (Saido42). *V*, Vessels. Scale bar, 50 μ m.

Figure 3. Quantitative image analysis of 10G4 A β -ir deposits in brain sections of rats infused with A β 40 alone or A β 40 plus leupeptin (*leu*) or A β 40 plus aprotinin (*apro*). Compared with A β 40 alone, coinfusion with either protease inhibitor resulted in statistically significant increases in the number of plaques per section in the thalamus (*A*) and the total A β -ir per whole-brain section (*B*), whereas only leupeptin plus A β 40 resulted in an increased mean plaque diameter per whole-brain section (*C*). Lower case letters above the columns indicate values that are significantly different from *a* (A β alone), *b* (leupeptin + A β), or *c* (aprotinin + A β). Error bars represent SD.

high resolution of plaques and the analysis of multiple plaques in one field. Results from this analysis revealed the average diameter of the plaque, number of plaques, location of plaques, and total immunoreactive A β area per plaque region (hippocampus, thalamus, or cortex). Plaque diameter was defined as the projected diameter of the plaque if

the total area of the plaque was converted to a circle with the same total area: ($2 \cdot \text{square root} [\text{total area}/3.1426]$). Data from the image analysis macros were exported to an EXCEL file for appropriate formatting before being exported to SuperANOVA (1.11) or StatView (version 4.5, Abacus, Berkeley, CA) on a Power Macintosh for statistical analysis.

Figure 4. *A*, Phosphotyrosine (PT; brown) double labeling with 10G4 A β -ir (blue) was used to determine the degree of A β -associated microglia. The area shown here is adjacent to the cannula track where three amoeboid PT-positive cells can be seen in a rat infused with A β 40 alone. Double-labeling sections from a leupeptin plus A β -treated rat for cathepsin B (brown) and A β (10G4; blue) revealed various degrees of overlap of A β (B) with cathepsin B, containing neurons ranging from apparently healthy cells showing only cathepsin B to occasional cells containing both cathepsin B and A β -ir (purple). *C–E*, Cells with grossly enlarged cathepsin B-positive granules and more diffuse cathepsin labeling as well as polarized clusters of intensely A β -ir-enlarged granules. *F, G*, Choline acetyltransferase-ir (blue) and TUNEL labeling of nuclei (brown) in the septum. The arrowhead shows a ChAT-ir neuron with TUNEL nuclei blebbing. *G, Inset*, Higher magnification. Scale bars: *A–E*, 25 μ m; *F, G*, 50 μ m.

RESULTS

Selection of protease inhibitor candidates

In preliminary experiments (data not shown) we screened a battery of protease inhibitors for their ability to inhibit the degradation of soluble A β 40 by 10 $\times$ concentrated serum-free media conditioned by human fetal astrocyte cultures. A β degradation was monitored by the time-dependent disappearance of A β -immunoreactivity (A β -ir) on Western blots labeled with 10G4 antibody. In these experiments the serine protease inhibitor apro-

tinin was an effective inhibitor of the loss of 10G4 A β -ir incubated with astrocyte-conditioned media. Metalloprotease inhibitors like EDTA and 1,10-phenanthroline also showed significant inhibition, but their marked toxicity ruled out their use in our long-term infusion experiments. Because we previously had found that leupeptin was an effective inhibitor of A β degradation by microglia and others had shown that the degradation of A β -containing peptides in cultured cells is reduced by leupeptin (Cole et al., 1992; Golde et al., 1992), this agent also was selected.

Figure 5. Results of quantitative image analysis of sections taken 0.8 mm posterior to the cannula site, where the maximum number of deposits was induced. Injury represents results from vehicle-infused animals. *A*, Shown is the analysis for GFAP as the percentage of GFAP-ir area per field. Leupeptin plus A β 40 increased and aprotinin alone decreased the percentage of GFAP as compared with all other groups. The mean area of GFAP-ir cells (*B*) was decreased by aprotinin relative to A β alone but was not altered by leupeptin. *C*, Shown is the analysis for microgliosis as the percentage of PT-ir area per field. Aprotinin plus A β , leupeptin, and leupeptin plus A β increased microgliosis, as compared with A β alone. Error bars represent SE.

As in previous A β 40 infusion experiments (Frautschy et al., 1996), plaque-like A β -ir was limited to a few scattered, small, diffuse deposits in animals infused with A β 40 alone. In contrast, the inclusion of protease inhibitors, notably leupeptin, resulted in numerous plaque-like deposits in cortex, hippocampus, and thalamus. Figure 1 illustrates A β -ir plaque-like deposits in the hippocampus and cortex. Figure 1*C* shows the intracellular A β -ir accumulation observed in the leupeptin plus A β -treated rats, including punctate labeling of processes extending from the A β -containing cells (Fig. 1*C*, arrows), which is a higher magnification

of the field shown in Figure 6*F2*. Figure 1, *D* and *E*, shows how the addition of leupeptin to A β -infused rats resulted in more A β -ir cell staining. Similar deposits were seen with 4G8, which appeared to detect 75% of the plaques stained for 10G4 (data not shown). To gain insight into the peptide species being stained by 10G4 and 4G8, we used confocal microscopy staining both for an end-specific antibody to A β 42 (FITC) and in conjunction with 10G4 (rhodamine). Although 10G4-ir and A β 42-ir colocalized in some regions, notably in selected neurons in the septum (Fig. 2*A*, arrowhead) and vessels, extracellular diffuse plaques did not stain for A β 42 (Fig. 2*A*, inset). Other cells contained two compartments of A β -ir: intracellular staining of 10G4-ir alone (Fig. 2*A*, arrows), surrounded by periplasmic staining of both antigens. Figure 2, *B* and *C*, demonstrates the individual rhodamine and FITC channels of Figure 2*A*. Attempts to demonstrate the presence of intracellular A β 40 by using end-specific antibodies produced weak and ambiguous labeling (data not shown), possibly because lysosomal carboxypeptidases may have destroyed the majority of free A β 40 epitope.

Quantitative analysis of plaques showed that both aprotinin and leupeptin increased A β 40-induced A β deposition and that leupeptin had the more robust effect (Fig. 3). For example, compared with A β 40 alone, aprotinin plus A β 40 resulted in both a statistically significant increase in total A β -ir area (Fig. 3*B*) per whole-brain section and an increase in the number of deposits in the thalamus (Fig. 3*A*). Leupeptin plus A β 40 induced the largest increase in total A β -ir area and the number of deposits in thalamus (Fig. 3*A*) as well as in the hippocampus and cortex (data not shown). Unlike aprotinin, leupeptin increased plaque diameter in A β 40-treated rats (Fig. 3*C*). These results demonstrate that protease inhibitors can increase A β deposition in this model.

Activated microglia and reactive astrocytes were observed with PT (Fig. 4*A*) and GFAP (data not shown), respectively, and were assessed quantitatively. Figure 4*A* depicts PT-labeled microglia in and around the cannula site in animals treated with A β plus leupeptin. Three amoeboid microglia are apparent within the cannula tract as well as an enlarged microglia cell within the larger A β -ir plaque, in addition to many ramified microglia distal to the plaque and cannula tract. Reactive gliosis (GFAP and PT) were quantitated as indices of the tissue response to treatments. Anti-cathepsin B (brown) was used to label endosomes/lysosomes, followed by anti-A β labeling (blue). Although most neurons showed intense cathepsin B labeling (Fig. 4*B*) in the leupeptin plus A β -treated rats, occasional cells also showed significant and overlapping punctate blue-purple A β -ir without morphological evidence of degeneration. Other cells (Fig. 4*C–E*) had markedly enlarged cathepsin B-positive granules with some apparent diffuse labeling and intense A β -ir granules clustered in one region, suggestive of a loss of organization and degeneration.

Figure 5 shows the quantitative analysis of immunohistochemistry for GFAP-ir and PT-ir. As shown in Figure 5*A*, the experimental infusions resulted in a similar level of astrogliosis that was decreased in the aprotinin-alone animals and markedly increased in the leupeptin plus A β group. An A β -induced increase in GFAP-labeled astrocyte cell size, suggesting the hypertrophy of cells, was attenuated by aprotinin (Fig. 5*B*). In contrast, aprotinin plus A β increased the microgliosis relative to injury or A β or aprotinin alone, consistent with a microglial response to extracellular A β . Both leupeptin and leupeptin plus A β treatments resulted in similar levels of microgliosis, which was more than in all other groups except for aprotinin plus A β (Fig. 5*C*). The

Figure 6. An example of TUNEL labeling in the entorhinal cortex of leupeptin (*Leu*) plus A β -treated rats (*A*) versus A β 40 alone (*B*). Higher-power micrographs demonstrate the differential TUNEL nuclear labeling affected by *Leu* plus A β 40 (*C*) versus *Leu* alone (*D*). The irregular morphology of the densely labeled nuclei is consistent with nuclear damage. *E*, *F*, TUNEL and A β labeling in adjacent sections. Most commonly, the A β deposits (arrows) are not coincident with, but are central to, the TUNEL-stained cells in deposits that are hypocellular, as in *E1* and *E2*. Occasionally, TUNEL-positive cells are found in the area of A β deposits, as shown here in the entorhinal cortex (*F1*, *F2*). Note the boxed area that shows the intracellular A β -immunostained cells depicted at higher power in Figure 1*C*. Scale bars: *A–D*, 200 μ m; *E*, *F*, 50 μ m.

increased microgliosis with leupeptin alone is consistent with a toxic effect.

To evaluate the persistent toxic effects of treatments in sections taken after 1 month of infusion, we chose the TUNEL method as an index of DNA damage. Although increased TUNEL labeling can be indicative of apoptosis, we use it here as a quantitative index of damage resulting from DNA fragmentation. TUNEL labeling revealed increased staining in patches and neuronal layers in cortex and hippocampus of A β -infused animals, which clearly was increased by leupeptin coinjection. Figure 6, *A* and *B*, depicts examples of this labeling in the entorhinal cortex. Figure 6, *C* and *D*, illustrates a higher magnification of TUNEL-labeled nuclei in the frontal cortex. Many of the densely labeled nuclei were irregularly shaped and appeared to be degenerating. The TUNEL-positive cell population of leupeptin plus A β appeared larger than that of the leupeptin-alone group, suggesting that A β was influencing a large cell population. TUNEL-labeled patches (or layers) of cells were sometimes (Fig. 6*E1*, *E2*), but not typically (Fig. 6*F1*, *F2*), coincident with A β deposits in this model.

Quantitation by image analysis of TUNEL-positive nuclei was performed in neuronal layers of the piriform and frontal cortex (Fig. 7). The density of TUNEL-labeled nuclei in both regions was increased by A β infusion and reduced by the inclusion of

aprotinin, which was neuroprotective. In contrast, leupeptin increased the TUNEL labeling associated with A β infusion in both the frontal cortex and, even more dramatically, in the piriform cortex. Analysis showed that the TUNEL area stained per nucleus was 30% of the total nuclear area. The A β plus leupeptin group and A β -treated groups were associated with larger nuclear area stained (Fig. 7*C*), presumably because larger nuclei such as neurons were being stained.

Finally, as an additional index of neurodegenerative changes in treated animals, sections were labeled with AT8, an antibody to phosphorylated tau protein (serine 202) found in neurofibrillary tangles and dystrophic neurites. In the leupeptin plus A β -treated rats, but not in other treatment groups, AT8-ir cells were identified in the hippocampus and entorhinal cortex as being associated with large diffuse plaques (Fig. 8).

DISCUSSION

Unlike leupeptin, aprotinin does not enter cells readily, yet both aprotinin and leupeptin increased the plaque-like deposition of intraventricularly infused A β . Only leupeptin plus A β caused the intracellular accumulation of A β -ir and increased toxicity, raising the possibility that the rate of intracellular degradation may limit toxicity.

Figure 7. Results of image analysis of TUNEL-labeled nuclei density in neuron layers of the piriform layer II (*A*) and frontal cortex layers II–III (*B*). Leupeptin exacerbated and aprotinin protected against A β -associated toxicity in both regions. *C*, Nuclear area per cell labeled with TUNEL in layers II–III of the frontal cortex demonstrates that, in the A β 40 and A β 40 plus leupeptin groups, TUNEL labeled a larger area per nucleus. [Counterstaining with hematoxylin shows that TUNEL is labeling an average of 30% of the nuclear area.] Error bars represent SE.

A β immunoreactivity

Because plaque A β -ir with various A β antibodies was increased by the infusion of A β peptide, was blocked by preabsorption with A β 42, and was not stained by amyloid precursor protein (APP) antibodies, the A β 40 infusion-dependent increases in A β -ir likely represent, at least in part, A β . However, it cannot be ruled out that some of the staining represents an accumulation of A β plus leupeptin infusion-dependent C-terminal APP fragments that contain 10G4 and 4G8 epitopes. This supports data from culture experiments showing that these protease inhibitors reduce A β degradation (data not shown).

Leupeptin effects on A β -ir

Leupeptin inhibits lysosomal degradation of A β or A β -containing peptides, and coinfusion of leupeptin increases A β deposition.

We also have found that the coinjection of leupeptin into rodent brain reduces the loss of A β detected by sandwich ELISA (our unpublished observations). Leupeptin is well known to inhibit the thiol cathepsins B, H, and L, calpain, and some serine proteases, like trypsin. A likely explanation is the inhibition of cathepsin B, a protease that has been shown to degrade A β and that has high carboxypeptidase activity at acidic pH (MacKay et al., 1997). Because the leupeptin effects correlate with the endosome labeling of A β , we believe the primary effects that were observed are lysosomal. Because calpain may increase A β 42 *in vitro* (Yamazaki et al., 1997) and can cause tau staining (Rebeck et al., 1995), we cannot eliminate that calpain inhibition is involved in our observed effects, although it would be difficult to explain how cytosolic calpain could have access to A β . Leupeptin does not inhibit cathepsin D, a lysosomal aspartyl protease that cleaves A β between residues L34–M35 and F19–F20 and F20–F21 (Hamazaki, 1996; McDermott and Gibson, 1996) that is responsible for the major A β -degrading activity in extracts of human brain (Hamazaki, 1996; McDermott and Gibson, 1996).

Intracellular A β , leupeptin, and toxicity

Intense A β labeling of enlarged cathepsin B-positive granules is consistent with a degenerative process in which affected cells build up A β -ir. Individual cells with gross accumulations of A β -ir and degenerative morphology illustrate a pathological progression (see Fig. 4*B–E*). Because only some enlarged granules (see Fig. 4*C–E*) are intensely A β -ir, the colocalization could represent the massive accumulation of A β peptide fragments within individual or fused endosomes or lysosomes in which seeding has occurred. In AD brain 4G8 labels secondary lysosomes and lipofuscin (Bancher et al., 1989), and the intracellular accumulation of ApoE correlates with the intracellular accumulation of A β and cell death (LaFerla et al., 1997). These data suggest that leupeptin reduces intracellular A β degradation, which may promote A β toxicity *in vivo*.

Aprotinin effects on A β -ir

APP contains a serine protease inhibitor domain (Cole et al., 1991). α -1 antichymotrypsin, α -1 trypsin, and other serpins are in plaques (Gollin et al., 1992), raising the possibility that the inhibition of serine proteases could promote A β deposition. Serine proteases prepared from human brain (Matsumoto et al., 1996), as well as trypsin-like serine proteases (Yang et al., 1995; Burdick et al., 1997), effectively degrade A β . Aprotinin, a broad spectrum serine protease inhibitor, can be used to examine extracellular A β degradation because it does not enter cells readily. Aprotinin-induced increase in A β deposition is consistent with the involvement of extracellular serine proteases in A β degradation. Our *in vivo* data for the neuroprotective effects of aprotinin on A β -induced TUNEL support previously reported neuroprotective effects of serpins in A β toxicity (Schubert, 1997). Unlike leupeptin plus A β , aprotinin plus A β does not cause the intracellular accumulation of A β . Although both protease inhibitors increase deposition, their differential effects on toxicity suggest the significance of intracellular A β accumulation in A β toxicity.

Other A β toxicity studies

Intraventricular A β infusion allows for the evaluation of persistent effects of A β far from an injection site and after the initial response to injection trauma has subsided. We chose TUNEL as an index of ongoing toxicity that could detect strand breaks caused by A β -induced oxidative damage. TUNEL staining allows for the detection and quantification of nuclei with excessive DNA

Figure 8. AT8 phospho-tau and A β immunostaining in the entorhinal cortex and adjacent thalamus of a leupeptin plus A β -treated rat. *A, B*, Depicted are two adjacent sections immunostained for 10G4 and AT8 phospho-tau, respectively. These low-magnification sections are depicted at higher magnification in *D* (10G4) and *E* (AT8). The *black-lined box* in *E*, shown at higher magnification in *C*, corresponds to the plaque labeled by the *black asterisk* in *D*. The *white-lined box* in *E*, shown at higher magnification in *F*, corresponds to the plaque labeled by the *white asterisk* in *D*. Similar AT8/A β colocalization was found in the hippocampus. Scale bar, 100 μ m.

fragmentation. The TUNEL-positive cells evaluated in the piriform cortex are predominantly neurons, because this is a dense neuron layer. TUNEL-positive neurons in the septum were identified by double labeling (see Fig. 4*F,G*). The A β -induced increase in TUNEL-positive nuclei in the frontal cortex was visualized in cells with larger nuclei than those affected by leupeptin alone (presumably neurons; see Figs. 6*B,C*, 7*C*). Although we cannot eliminate the possibility that A β affects TUNEL in glia, this evidence suggests that A β can increase TUNEL staining in neurons. Coinfusion of leupeptin exacerbates and coinfusion of aprotinin alleviates A β 40 toxicity.

As an indirect measurement of toxicity, we evaluated GFAP-ir

astrocytes and found that leupeptin plus A β 40 increased total GFAP-ir cortical area as compared with A β 40, whereas aprotinin plus A β 40 reduced astrocyte cell size. This strengthens the results observed with TUNEL, suggesting a possible glial response to neuron (DNA fragmentation) damage. We also examined PT-labeled microglia, which become hypertrophied in plaques of APP_{sw} mice (Frautschy et al., 1998). In our model we observed a less dramatic but significant hypertrophy of microglia, especially in the large diffuse A β deposits (see Fig. 4*A*). Both leupeptin and aprotinin increased the microglial response to A β despite the apparent neuroprotective effects of aprotinin. This may reflect effects of the protease inhibitors and A β on microglia that are

independent of neuron damage. Nevertheless, the observed A β -dependent increases in TUNEL and persistently increased astrogliosis support ongoing A β -associated toxicity.

There is now extensive literature showing that high levels of aggregating or fibrillar A β can be toxic to isolated neurons or cell lines in culture (Yankner et al., 1990; Yankner, 1996; Blanc et al., 1997). When high levels of A β are focally injected into rats with the use of toxic solvents, acute toxicity occurs at the injection site (Kowall et al., 1991); injection of fibrillar A β can lead to a selected loss of some neurons (Weldon et al., 1998), but the relevance of these models is unclear (Waite et al., 1992). *In vivo* results, using lower doses and nontoxic solvents, demonstrate negative or equivocal toxicity (Kosik and Coleman, 1992; Winkler et al., 1994). APP transgenic mice, which accumulate high levels of deposited A β , have not shown quantifiable neuron loss (Irizarry et al., 1997). It is unclear whether this relates to reduced toxicity in rodents or other factors such as the overexpression of APP, which may exert neurotrophic effects.

Our results suggest an alternative explanation for limited A β toxicity in young rodent models. Infused soluble A β is removed or degraded readily, which may explain why few persistent deposits are found in the absence of additional cofactors (Snow et al., 1994; Frautschy et al., 1996). Rodent A β aggregates as readily as human A β (Hilbich et al., 1991); therefore, with aging, the persistence of effective A β clearance mechanisms also may be a major reason why rodents normally do not develop age-related A β deposits.

Other effects of protease inhibitor infusions

Chronic intraventricular infusion of leupeptin, but not aprotinin, induces the formation of lysosome-derived lipofuscin (Ivy et al., 1989a). In contrast to saline, leupeptin infusion also causes the accumulation of tau and ubiquitin (Ivy et al., 1989b), APP C-terminal fragments (Hajimohammadreza et al., 1994), and intraneuronal A β -ir (Mielke et al., 1997) and reduced ChAT, somatostatin, and neuropeptide Y (Kuki et al., 1996). Ultrastructural analysis demonstrated the appearance of dense-body packed dystrophic neurites (Kuki et al., 1996) and paired helical filament (PHF)-like structures (Takauchi and Miyoshi, 1995). Why we failed to see increased APP C-terminal immunostaining with leupeptin treatment remains unclear but could reflect methodological differences in tissue preparation or time course because of our longer infusion. Acute uptake of A β 1–42 aggregates by endosomes or lysosomes can induce C-terminal fragments (Yang et al., 1995). Because of the possible resemblance of these results to changes found during normal aging and AD, it is possible that leupeptin-induced changes in lysosomes may overlap with these phenomena.

Because the formation of lipofuscin from lysosomes is a common and well confirmed structural age change in postmitotic cells, studies of age-related changes in lysosomal enzymes and lysosomes have looked for and found defects in aged rodent brains (Nakamura et al., 1989). Widespread alterations in neuronal endosomes and lysosomes in AD occur at early stages, far in excess of changes in other neurodegenerative conditions (Cataldo et al., 1994, 1996, 1997). Despite the activation and proliferation of the endosomal and lysosomal system in AD, it is unable to prevent the accumulation of A β deposits. A β aggregates accumulate in the lysosomes of cultured cells and may seed further aggregation of A β at low pH (Burdick et al., 1997), whereas neurotoxicity associated with A β 42 treatment upregulates cathe-

psins and causes leakage of lysosomes (Yang et al., 1997). A β 42 is particularly resistant to degradation (Yamazaki et al., 1997), especially in its fibrillar form (Nordstedt et al., 1994).

Conclusions

These *in vivo* coinfusion studies demonstrate that protease inhibitors can increase A β infusion-induced plaque-like A β -ir deposits. Tests are underway that use more specific inhibitors of putative A β -degrading enzymes in brain. Our results show evidence of widespread A β toxicity in the infusion model, contrasting neuroprotective and neurotoxic effects of aprotinin and leupeptin, both of which increase A β deposition. Finally, our toxicity data are consistent with a role for the uptake of intracellular A β into the endosomal/lysosomal system *in vivo*, which may be attributable, in part, to the induction of endosomal accumulation of toxic A β 42.
