Morphology and Growth Patterns of Developing Thalamocortical Axons

Irini Skaliara, Richard Adams, and Colin Blakemore

University Laboratory of Physiology, University of Oxford, Oxford OX1 3PT, United Kingdom

It is increasingly evident that the actions of guidance factors depend critically on the cellular and molecular context in which they operate. For this reason we examined the growth cone morphology and behavior of thalamic fibers in the relatively natural environment of a slice preparation containing the entire pathway from thalamus to cortex. Axons were labeled with Dil crystals and imaged with a laser-scanning confocal microscope for up to 8 hr. Their behavior was analyzed in terms of morphology, extension rates, shape of trajectory, frequency of branching, and percentage of time spent in advance, pause, and retraction. Thalamic fibers had distinct and stereotyped growth patterns that related closely to their position; within the striatum growth cones were small and elongated, rarely extending filopodia or side branches. Axons grew quickly, in straight trajec-

ries, with minimal pauses or retractions. When they reached the ventral intermediate zone, axons slowed down, often coming to a complete stop for up to several hours, and their growth cones became larger and more complex. During pauses there were continuous extensions and retractions of filopodia and/or side branches. When advance resumed, it was often to a different direction. These results demonstrate consistent regional variations in growth patterns that identify an unexpected decision region for thalamic axons. They provide the basis for examining the roles of guidance cues in an accessible yet intact preparation of the thalamocortical pathway and allow for an evaluation of previously suggested pathfinding mechanisms.

Key words: growth cones; development; axon guidance; time-lapse confocal imaging; pathfinding; in vitro; thalamocortical

One of the most critical steps in the development of the CNS is the formation of the precise and stereotyped axon pathways that connect different structures to their targets. Despite the plethora of studies on axon guidance, the mechanisms that axons use to navigate through complex cellular environments such as the thalamocortical pathway remain elusive. Tracing studies in fixed brains have revealed the time course and morphological characteristics of axonal development and target invasion (Crandall and Caviness, 1984; Catalano et al., 1991, 1996; Ghosh and Shatz, 1992b; Agmon et al., 1993, 1995; Kageyama and Robertson, 1993; Miller et al., 1993; Schlaggar and O'Leary, 1994; Métin and Godement, 1996; Molnár et al., 1998), whereas in vitro experiments have indicated (1) the influence of target-derived factors on axon outgrowth (Yamamoto et al., 1989, 1992, 1997; Molnár and Blakemore, 1991, 1999; Bolz et al., 1992; Emerling and Lander, 1994; Hubener et al., 1995; Tuttle et al., 1995; Métin and Godement, 1996) and (2) the effects of specific guidance molecules on axons from cortical explants (Métin et al., 1997; Richards et al., 1997; Bagnard et al., 1998; Polleux et al., 1998). Although such studies of the thalamocortical pathway have revealed valuable information, they have always examined axons outside their natural environment. However, it is increasingly evident that guidance factors act in combination with other molecules and that their specific role depends on the spatiotemporal context in which they operate (Colamarino and Tessier-Lavigne, 1995; Stoeckli

and Landmesser, 1995; Püschel et al., 1996; Tuttle and O'Leary, 1998; Winberg et al., 1998; Hornberger et al., 1999; Isbister et al., 1999; Rose and Chiba, 1999).

There is considerable evidence that growth cone morphology, especially when examined together with the accompanying behavior, reflects the nature of the immediate local environment. For instance, growth cones tend to become larger and more complex when confronted with divergent pathways, the so-called decision regions of navigation, as opposed to nondecision regions, where growth cones are slender and streamlined (Raper et al., 1983; Tosney and Landmesser, 1985; Caudy and Bentley, 1986a; Bovolenta and Mason, 1987; Holt, 1989; Godement and Mason, 1993; Halloran and Kalil, 1994). Additionally, alterations in growth cone morphology have been correlated with interactions with cellular landmarks, often leading to modifications in trajectory (Caudy and Bentley, 1986b; Bovolenta and Dodd, 1990; O'Connor et al., 1990). Hence, by directly examining the dynamic morphology and growth patterns of thalamic growth cones, we can gain critical insight into the pathfinding mechanisms used by these axons.

Here we have investigated, for the first time, thalamic fibers in their intact cellular and biochemical environment, in a slice preparation that includes the ventrolateral thalamus and somatosensory cortex (Bernardo et al., 1986; Agmon and Connors, 1991). The changes in morphology and behavior of thalamic growth cones, as they advance through distinct cellular milieus, have provided clues to the mechanisms used by these axons to navigate toward their targets.

MATERIALS AND METHODS

Animals. Rat embryos of known gestational ages [embryonic day (E)15.5–E18] were obtained from an in-house breeding colony. The day of vaginal plug detection was considered as E0.

Surgical procedures. Embryos were delivered by caesarean section from

pregnant rats deeply anesthetized with an intraperitoneal injection of Nembutal (100 mg/kg). The brains were dissected in cold saline (HBSS, Sigma, St. Louis, MO) supplemented with extra glucose (to a final concentration of 6.0 gm/l) and embedded in 3% low melting agarose. Whole forebrain slices, including the ventrolateral thalamic nucleus and somatosensory cortex, were obtained by using a procedure modified from the literature (Bernardo et al., 1986; Agmon and Connors, 1991). Brains were embedded and placed with the ventral face down; a vertical cut through the tissue was made at a 35–45° angle to the midline (depending on the age of the animal) through the most anterior part of the brain. The tissue rostral to the cut was discarded, and the remaining tissue was glued on to the vibratome stage. Slices were cut at a thickness of 400 μ m and left to equilibrate at room temperature for 30–60 min. We examined the slices under transillumination and selected those with clearly visible fiber bundles traversing the striatum, running between the ventrolateral thalamus and the lateral part of the putative somatosensory cortex. Then these slices were transferred to poly-L-lysine-coated Petri-Permunt dishes containing F12-DMEM medium (Sigma), supplemented with N2 (1 ml/100 ml, Life Technologies, Gaithersburg, MD), glucose (6 gm/l), L-glutamine (1.25 ml/100 ml), and antibiotics (penicillin–streptomycin, 1 ml/100 ml; Sigma). Five to eight such preparations from different embryos of the same litter were made for each experiment and kept in a 5% CO₂ humidified incubator at 37°C. In all experiments 3% calf serum was added to the medium in one-half of the dishes. No differences in axon outgrowth were found between the two conditions, and the data are pooled.

DiI labeling. Thalamic axons and their growth cones were labeled by the insertion of minute crystals of the carbocyanine dye DiI (1,1'-diiododecyl-3,3,3',3'-tetramethylindocarbocyanine perchlorate; Molecular Probes, Eugene, OR) into the thalamus with a tungsten needle under a dissecting microscope. In such diagonally cut slices, with visible fiber bundles traversing through the striatum, the part of the thalamus present in the slice consists of the ventrolateral thalamic nucleus (Bernardo et al., 1986; Agmon and Connors, 1991). The slices were returned to the incubator and left overnight to allow for dye transport. With this method we were able to obtain small numbers of labeled thalamic axons in each slice (1–20), which were clearly identifiable and could be traced for long distances back toward the thalamus.

Time-lapse imaging of thalamic axons. Examination of the fluorescently labeled axons was performed with a confocal microscope to obtain clear optical sections within the relatively thick specimen. Most experiments were done on a Leica Fluovert confocal microscope (Nussloch, Germany), except one experiment that was done on a Bio-Rad confocal microscope (Richmond, CA). The dishes were scanned quickly under low power to identify slices that contained well labeled thalamic fibers and an uninterrupted pathway. After a preparation was selected, the dish was sealed and placed on the heated stage of the microscope maintained at 35°C with a thermostatically controlled heater. The medium was changed every 5–8 hr. At the end of the imaging session the slices were fixed in a 4% paraformaldehyde solution for 24–48 hr for subsequent verification of the location of the imaged fibers.

We focused our analysis of thalamic axons on two regions of the thalamocortical pathway (see Fig. 1). The first is the part of the primordial internal capsule (IC) within the developing corpus striatum (ganglionic eminence); the second is the ventral intermediate zone (VIZ), at the border between the basal and dorsal telencephalon. Individual fibers and growth cones were observed with water immersion objectives [Leitz 25 $\times$, PL Fluotar, numerical aperture (NA) 0.75; 50 $\times$ NA 1.0] for up to 9 hr. Single frames or stacks of images at different depths were obtained at given time intervals ranging from 1 to 10 min. In the first case the pinhole was open to maximize the thickness of the optical section and minimize the required laser intensity. Several frames (usually four) were averaged. The data points on the graphs (see Figs. 2–4, 6–8) represent the axon length at the times the images (either single frames or stacks) were collected. Although images were collected at regular intervals, in cases in which the axon length did not change between one frame and the next, data points sometimes were omitted from the final graph for reasons of clarity. Every effort was made to maximize the stability of the preparation and to maintain a constant focal plane during the experiment. However, it still proved necessary to adjust the focus periodically, because axons inevitably moved at variable angles to the plane of the slice. Frames in which the growth cones had moved out of focus during a particular sequence were excluded from calculations of growth rates. Confocal images were transferred to a Macintosh computer and analyzed

further with the National Institutes of Health IMAGE software (Bethesda, MD).

Technical considerations. One of our concerns was to ensure that the analyzed axons and growth cones were healthy and representative of fibers growing in the intact brain. For these reasons axons were *excluded* from the study if any of the following applied: (1) beaded appearance, which might indicate photo damage induced by exposure to the fluorescent light; (2) growth cone escaping to the surface of the slice—to avoid artifacts induced by the cutting procedure, all imaged growth cones included in the analysis were located at least 30 μ m deep into the slice; (3) steady and gradual changes in rates of growth, because this could indicate a gradual deterioration of the axon attributable to either the culture conditions or damage induced by the laser. Furthermore, all imaging sessions began at least 12 hr after preparation and labeling of the slices to avoid monitoring growth cones severed from the parent cell body (Harris et al., 1987).

Analysis. The behavior of axons was analyzed in terms of growth cone morphology, rates of growth, and percentage of time spent in extension, pause, and retraction. The length of the distal segment of the axon was measured from a distinctive point along the axon, such as a branch point or distinct inflection (but not a varicosity as these often were seen to move within the axon shaft), to the distal tip of the growth cone. For these measurements the outline of the axon was followed with the mouse cursor on the screen to obtain the *real* length of the axon, beyond the reference point. We chose this procedure, instead of marking only the final position of the growth cone, to avoid errors attributable to movements of the entire slice in the dish. These length values were divided by the total observation time to give a value for the net overall *rate* of advance. As an independent measurement the rates of growth were also calculated separately for shorter, defined periods for comparison between different growth patterns. These “instantaneous” rates were determined over periods of at least 10 min to avoid miscalculations attributable to “imaging noise” (i.e., the tip of the growth cone moving in and out of the focal plane). To determine growth cone *activity* (even if not accompanied by forward extension), we measured the total length of all visible side branches and filopodia. Finally, to assess the percentage of time spent in advance, pause, or retraction, we plotted the normalized axon length from each frame as a function of time; the duration of time spent in each mode was expressed as a function of the total time of observation.

RESULTS

Whole forebrain slices obtained from embryonic rats between E15.5 and E18 were labeled with DiI crystals placed in the thalamus, cultured overnight, and monitored with time-lapse confocal microscopy over the next 2–30 hr. In each slice a small number of fibers were labeled, and their growth cones were located at various positions along the thalamocortical pathway. All thalamic axons studied here ($n = 25$) followed a trajectory similar to that taken *in vivo*, initially extending anterolaterally out of the diencephalon and then turning dorsally through the developing striatum, within the primordial internal capsule. Axons that “escaped” to the surface of the slice often grew in aberrant directions and were excluded from the study. We concentrated our observations in two areas: (1) the segment of the internal capsule (IC) within the developing corpus striatum and (2) the adjacent ventral intermediate zone (VIZ) forming the transition region between the basal telencephalon and the cerebral wall (Fig. 1).

Most of the sequences that we studied were restricted to one locale, but occasionally we were able to follow growth cones over two consecutive locales, either as they moved from the IC into the VIZ or as they moved on from the latter to make their way toward the overlying cortex. The behavior of the axons in these two regions was analyzed in terms of growth cone morphology, shape of trajectory, rates of growth, and percentage of time spent in extension, pause, and retraction, measured over consecutive 5 min periods. Growth cone “activity” refers to dynamic morpho-

Figure 1. Photomicrograph, taken under transillumination, of a 400 μm whole forebrain slice from the left hemisphere of an E17 rat brain cut at 45° to the coronal and sagittal planes. Broken lines enclose the two locations in which growing axons were monitored: *a*, the region of the internal capsule; *b*, the ventral intermediate zone at the border between dorsal and ventral telencephalon. logical changes of the growth cone, including extensions of filopodia and side branches in the most distal portion of the axon.

Growth patterns along the thalamocortical path

Thalamic fibers principally manifested three quite distinct types of behavior, which we call “tracking,” “elongation,” and “exploration.” To be classified in one of these categories, an axon had to display a particular behavior (see criteria below) for a minimum of 30 min—and in all but one case they did so for a period of at least 1 hr. These growth patterns were highly stereotyped, and most axons (22 of 25) manifested only one type of behavior. The remaining three axons, all of which were studied for particularly long periods (6–8 hr), showed evidence of transition between two behavioral patterns (see below). In these three cases the observation period was divided in two sequences, which were, for the purpose of classification, considered separately.

When classified as **tracking** ($n = 5$ sequences), axons advanced in straight trajectories, as if moving along preexisting “tracks.” Their growth cones were small (1–6 μm), sometimes not much wider than the diameter of the parent axon, and had simple morphology: spherical or elongated shape with no visible side branches or filopodia. They did not shift their direction, nor did they show signs of exploring the surrounding area but spent most of the time in forward extension, with few pauses and rare retractions (Fig. 2, *side panels*). Occasionally, a growth cone appeared to be growing in close association with another labeled axon that had already traversed the region. However, in such cases, wherever three-dimensional reconstruction was possible, the two neurites were found to be located in different focal planes, the illusion of an association between them being created by the similarity in the direction of their growth. Nevertheless, the possibility cannot be excluded that axons manifesting this behavior were fasciculating on other fibers that were not labeled. Examples of this tracking pattern are illustrated in Figure 2*A*, in which changes in normalized axon length are plotted as a function of time for two thalamic fibers from separate experiments.

The bottom graph describes the first hour of the imaging session for one of these axons on an expanded time scale to illustrate the momentary pauses or retractions, which would not be discernible with lower sampling frequencies (Fig. 2*B*).

Axons displaying **elongation** behavior ($n = 11$ sequences) also advanced steadily, with only short pauses and minimal retractions, but along a meandering rather than a straight trajectory (Fig. 3*A,B*). The growth cones, although still relatively small and lacking extensive lamellipodia or filopodial protrusions, were more elaborate and less uniform (Fig. 3, *side panels*), occasionally bifurcating transiently or emitting small side branches that were retracted rapidly.

In marked contrast to the growth patterns described so far was the **exploration** behavior ($n = 12$ sequences). Axons in this mode spent a much larger percentage of time pausing and/or retracting and, consequently, displayed considerably slower net advance. In addition, their growth cones were large (often up to 15 μm in diameter) with a complex and irregular morphology, characterized by multiple filopodia and side branches extending in one or more directions (Fig. 4, *top and bottom panels*). The growth cone itself frequently bifurcated (Fig. 4, *top middle panel*) and occasionally even assumed a tripartite appearance (Fig. 4, *top, second panel*), although this was never seen to lead to bifurcation of the entire axon. Filopodia and lamellipodia were usually present at the growth cone, within 20 μm of the most distal tip of the axon. Occasionally, similar spiky and veil-like protrusions emerged from more proximal locations along the axon shaft (Fig. 4, *bottom, second, and third panels*), sometimes as much as 60 μm behind the growth cone. As can be seen in these examples, growth cone morphology was highly dynamic and continuously changing, but it very rarely assumed the simpler, elongated form observed in elongation behavior (but see below).

In the exploratory mode the growth cones seldom collapsed, even during long pauses, but remained highly motile. The graph in Figure 4 illustrates the growth pattern of an axon in the VIZ over a period of 8 hr. The symbols indicate the *net distance* covered by the axon in the duration of the experiment—obtained by measuring the length of the axon from a defined and stable point along the axon shaft to the most distal tip of the growth cone proper—as a function of time. Negative numbers indicate a retraction with respect to the state of the axon at the beginning of the recording session.

For the first 6 hr the axon did not cover new ground and in fact had, during the first 2 hr, retracted from its initial position by ~ 20 μm . At the end of this period of hesitation, during which the growth cone did not collapse but remained large, florid, and very motile, the axon resumed its forward advance at a different orientation (Fig. 4, *last bottom panel*). This change in behavior was accompanied by a change in morphology as the growth cone converted to the more streamlined form that characterized axons in the “elongation” mode. This observation is reminiscent of the recent finding that the morphology of retinal growth cones is related to their behavior (Mason and Wang, 1997). The behavior of this axon is shown on an expanded time scale in Figure 5 to illustrate graphically the contrast between the lack of forward advance of the axon and the active remodeling of the growth cone. The top graph plots the change in total side branch activity; the lengths of all (visible) side branches (examples of which are indicated by the arrows in Fig. 4) and filopodia were measured at regular intervals, added together, and normalized to the beginning of the sequence. Such measurements were certainly an underestimate of growth cone activity, since it is not possible to

Figure 2. Thalamic fibers growing through the internal capsule (IC) in a slice from an E18 embryo. *A*, The *top graph* plots the growth of two axons (axons 4 and 6) for the duration of the recording sessions (3 and 4.5 hr, respectively). Measurements were made from extended-focus images collected at regular intervals (as indicated by the *red* and *blue* data points) and were normalized with respect to the measurements taken at the beginning of the sequence. *B*, Closer observation of the behavior of axon 4 over the first 60 min of the recording is shown on an expanded time scale in the *bottom graph*, each *dot* indicating the position of the leading tip of the axon relative to a distinctive and fixed reference point on the axon shaft. Single-frame confocal images were obtained at 90 sec intervals (gaps reflect loss of the focal plane). The *side panels* are single-frame images of axon 4 at selected times during the first hour of the recording session. The times at which the images were obtained are indicated at the *top right* of each frame. Both axons are advancing most of the time, with brief pauses (e.g., 20–30 min, in *B*) and occasional retractions (e.g., from 47 to 56 min, in *B*). Note the morphology of the growth cone, which is small and streamlined with no side branches. Scale bar, 10 μm .

capture all three-dimensional changes in lamellar shape and extensions of transient protrusions in single confocal frames. For comparison, the bottom graph plots the change in length of the principal axon over the same time period.

Within the population of fibers in the exploring category was a subgroup of axons (3 of 12) with different morphology. The leading tip of these axons was often small and streamlined, and there were one or more side branches emerging from the distal 40–50 μm of the axon shaft. These branches often had small (occasionally barely detectable) growth cones of their own and were extending and retracting continually as if probing the surrounding area. These neurites were transitory, with a life span of 5–65 min.

Figure 6 shows an example of such an axon. At the beginning of the recording session this axon already had one side branch at $\sim 40 \mu\text{m}$ behind the growth cone (Fig. 6, *top left panel*). During the observation period it had extended and retracted a further three side branches, while the principal axon as well as the original side branch (called the *main side branch* in Fig. 6) were pausing or retracting (Fig. 6, *side panels*). This behavior is illustrated in the graph, in which the normalized length of each of the branches is plotted separately as a function of time. Although

they did not have growth cones as large and complex as those illustrated in the Figure 4, these axons were classified as being in exploratory mode on the basis of their growth pattern, which was characterized by prolonged pauses and retractions and slow overall rates of advance. As in this example, whenever we directly observed the *emergence* of a new branch ($n = 5$), this always occurred while the main axon was pausing. Likewise, the majority of cases in which side branches extended or retracted occurred during a pause in main axon growth (e.g., Figs. 4, 6, 7).

Correlation between the behavior and location of growth cones

We then examined whether the morphology and behavior of growth cones correlated with their location within the pathway from thalamus to cortex. Although there were overlapping characteristics and behavioral patterns, some conclusions were immediately obvious. Simply by playing back the animated sequences we could see that, within the IC, axons displayed either “tracking” or “elongation” but never “exploration” behavior. Growth cones in this region never had the highly complex morphology often encountered in the VIZ—even during the brief periods when the axons did pause (see below), growth cones remained simple and

Figure 3. E16 thalamic fiber growing through the IC. *Side panels* are extended-focus images of the distal segment of the axon and its growth cone, collected at various times throughout a 3 hr imaging session. The axon has been outlined for clarity. The times at which the stacks were collected are indicated at the *top left* of each image, and the *star* indicates a stable point along the axon for clearer illustration of axon extension. The *top graph* shows that it advanced at a relatively constant growth rate. The *bottom graph*, at an expanded time scale, provides a better view of the momentary pauses and retractions. Scale bar, 10 μm .

relatively small. Axons very rarely formed branches either adjacent to the growth cone or further back along the axon shaft. In addition, they very seldom shifted their trajectory and never retracted for >10 – 15 μm . On the other hand, axons in the VIZ, even when advancing, never manifested the “growing-on-tracks” appearance. Their growth cones were always well defined and clearly distinguishable from the axon, and they did not advance in the absolutely straight trajectories encountered in axons of the tracking group. Most of them shifted directions at least once during the imaging session, and they routinely displayed extensive side branch activity, either from the growth cone itself (e.g., Fig. 7) or from the neurite shaft (e.g., Fig. 6) as they went through cycles of extension, pausing, and retraction. These qualitative differences (summarized in Table 1) were not related to the age of the animal from which the slices were prepared nor to the age of the slice once it had been removed from the animal.

To quantify further the extent to which particular behaviors

were correlated with discrete locations in the path, we analyzed the shape of trajectory and the extension rates for each axon as well as the percentage of time they spent in advance, pause, and retraction. The net extension rate was calculated as the total distance covered by the leading tip of the axon divided by the total time of observation, over sequences of at least 30 min. To determine the time spent in forward advance, pause, or retraction, we obtained the position of the distal tip of the growth cone proper from each frame and plotted it as a function of time. Then these values were used to calculate the fraction of all 5 min intervals in the sequence in which growth cones advanced, paused, or retracted.

Axons in the IC had relatively uniform extension rates ranging from 15 to 25 $\mu\text{m/hr}$, with a mean of 17.3 ± 4.4 $\mu\text{m/hr}$ ($n = 11$). In contrast, axons in the VIZ had more variable and significantly slower extension rates ranging from 2 to 16 $\mu\text{m/hr}$, with a mean of 8.4 ± 5.3 $\mu\text{m/hr}$ ($n = 16$). Interestingly, the “instantaneous”

Figure 4. Thalamic axon with its growth cone located in the ventral intermediate zone (VIZ) of an E17 forebrain slice. *Panels* at the top and bottom are single confocal frames obtained at the times indicated. These images are framed to illustrate growth cone morphology and do not necessarily reflect the absolute position of the growth cone with respect to the slice. The *graph* illustrates the behavior of this axon for the 8 hr of the imaging session. Measurements were made from a stable inflection point further down along the axon shaft and were normalized to the beginning of the sequence. *Dots* indicate the principal axon length, i.e., the distance from the measuring point to the leading edge of the body of the growth cone (excluding filopodia and side branches, examples of which are indicated by the *arrows* of the leading segment of the axon). Periods lacking data points reflect either loss of the focal plane or deliberate changes in the area that was imaged. Although the out-of-focus images were not sharp enough to allow for accurate measurements, they confirmed that the growth cone was still in the field of view and had not manifested massive extensions or retractions. Note that the net forward growth rate is at its highest at the end of the 8 hr imaging session, indicating the continuing good health of the slice. Scale bar, 10 μ m.

speed of growth during short periods of advance (5–30 min) was similar between axons in the two locales (Table 2), in each case sometimes reaching up to 100 μ m/hr. Indeed, when the average speed of growth was calculated separately for periods of extension alone, the rates for axons in the IC, although somewhat faster, were not significantly different from those in the VIZ.

This would seem to indicate that the twofold difference in net extension rates between the two groups of axons may be explained by a difference in the fractions of time spent in advance versus pause and retraction. Indeed, the duration of individual pauses in the internal capsule was between 5 and 50 min, whereas in the intermediate zone the pauses could last up to 6.5 hr. Furthermore, we found that axons in the VIZ spent approximately one-half as much time in extension and three times as

much time in pausing and withdrawing as compared with axons in the IC (Table 2).

Finally, we analyzed shifts in trajectory, defined as changes in the direction of forward advance of at least 20°. Only 1 of 11 axons in the internal capsule made such a turn, whereas close to one-half of the fibers in the VIZ (7 of 16) made single or multiple turns of between 20 and 50° (see Table 1). This was not a consequence of the duration of the imaging sessions, which was similar in the two groups (mean $\pm$ SD of the duration of sequences in the IC and VIZ, 153 $\pm$ 61 and 171 $\pm$ 99 min, respectively).

Interestingly, in the cases in which we were able to observe turning behavior directly, the mechanistic aspects of it were different between the two groups. Axons in the internal capsule

Figure 5. “Exploratory” behavior. The graphs illustrate on expanded time scales the behavior of the axon shown in the previous figure. The red symbols and line indicate the changes in total side branch length—i.e., the summed length of all visible filopodia and side branches of the leading tip of the axon. The blue symbols and trace indicate the principal axon length, i.e., the distance from a stable measuring point to the most distal tip of the body of the growth cone. Both measurements are normalized to the respective measurements made at the beginning of the sequence. Note the lack of net advance (blue trace) and the considerable “stationary” movement (red trace). Negative numbers in either case indicate retractions with respect to the position at the onset of the observation period.

shifted direction by gradually curving while in full extension (see Fig. 2, *side panels*). In contrast, axons located in the intermediate zone always changed their trajectory immediately after a pause, either by following one branch of a bifurcating growth cone or by making a sharp turn toward the side from which they had just withdrawn a side branch. The latter behavior is shown in the example in Figure 7, in which the extensions of the main axon and of the side branch are plotted separately to contrast their behaviors. At the onset of the sequence the main neurite is inactive with its growth cone in a collapsed state (Fig. 7, *left panel, open arrow*), whereas the side branch is highly motile, having itself bifurcated and with a veil-like structure protruding from one segment (Fig. 7, *left panel, filled arrow*). As the side branch gradually retracts back into the axon shaft, the principal neurite is activated progressively (Fig. 7, *second and third panels*). After 45 min the side branch is barely visible whereas the main axon continues to extend forward, having shifted its course by $\sim 45^\circ$ toward the direction previously taken by the side branch (Fig. 7, *right panel*). Although we were not able to follow this sequence long enough to determine whether the shift in direction constituted a persistent change in trajectory, this is precisely the course this axon (which was located in the VIZ) would have had to take to enter the overlying cortex.

Transitions of behavior

Having documented the close correlation between growth cone location and behavior, we then examined more closely all individual sequences of growth cones located at the borders of the IC and VIZ to see whether it was possible to detect transitions in behavior. We found three such cases. One example has been illustrated already in Figure 4 in which the axon, after having spent >6 hr in pause/retraction, a behavior clearly classified as exploration on the basis of the outlined criteria, then began to move more purposefully forward and its growth cone assumed a simpler and more streamlined shape. Hence, on the basis of the same criteria, the sequence after 385 min in Figure 4 was classified as elongation (see Fig. 4, *last panel*).

The other two cases of transitions were of the opposite sign, in which axons with small and simple growth cones, advancing at a fairly steady rate were, in the latter part of the recording, found to spend more time pausing and retracting. Such an example is illustrated in Figure 8, in which the net advance (normalized length) of the axon was plotted as a function of time. During the first hour of the recording the axon was extending fairly steadily, had a relatively simple morphology (Fig. 8, *first three panels*), and therefore was classified as elongating. However, in the remaining 5 hr of the observation time the axon slowed down, its growth

Figure 6. Side branch exploration of an axon for which the leading segment was in the VIZ, in a slice that was obtained from an E18 rat embryo. The four side panels are single-frame confocal images at selected times during a 30 min imaging session (times indicated at top left of each panel). The graph illustrates the behavior of each branch on this axon separately. Measurements for the principal axon and the main side branch were made from the point of bifurcation of the main side branch (star in top left panel) and normalized to the beginning of the recording session. The principal axon (green) as well as the main side branch (light blue) are primarily pausing, whereas side branches 2 (red), 3 (yellow), and 4 (black) along the axon shaft are being extended and retracted continually. The axon and branches in the four panels have been outlined for clarity. Scale bar, 10 μm .

cone became larger and more complex, and there were long pauses interrupted by momentary extensions and retractions, all distinguishing features of exploration behavior. In both examples of this type of transition the change in behavior was not attributable to a gradual deterioration of the slice because (1) the reduced extension rate was not accompanied by a collapsed growth cone; on the contrary, growth cones became enlarged and more elaborate, and (2) other axons in the same slice, imaged for comparable durations, did not show a similar reduction in growth rate.

Although rare, these transitional behaviors were particularly interesting because of the locations in which they were observed. The first example (transition from exploration to elongation) occurred at the lateral border of the intermediate zone as the growth cone was about to exit the VIZ and grow into the cerebral wall. The other two cases (transition from elongation to exploration) occurred at the border between the striatum and the cerebral wall as the growth cone was entering the VIZ. None of the remaining 22 sequences contained evidence of transitional behaviors.

DISCUSSION

This is the first report of the behavior of living thalamic axons as they grow toward their cortical targets in a slice preparation that contains the entire uninterrupted pathway between the thalamus and the cortex. We show that thalamic fibers follow the same trajectory as *in vivo* and exhibit distinct behaviors characteristic of the region through which they are growing. In the internal capsule they grow faster, in straight trajectories, with minimal pausing or

exploring the surroundings. Growth cones are small and simple, rarely extending filopodia or side branches. When they reach the ventral intermediate zone, they slow down, and the growth cones become larger and considerably more complex. Axons may even come to a complete stop, pausing for up to several hours. During these pauses the growth cones are usually at their most effusive, with continuous extensions and retractions of filopodia and lamellipodia. When net advance resumes, it is often in a different direction, appropriate to their final destination. These distinct behaviors can be interpreted in the context of multiple guidance cues and help in the evaluation of models of pathfinding, based on observations from fixed material and experiments in tissue culture.

Axon guidance within the striatum

What cues could account for the shapes and behaviors of growth cones that we observed in the IC? Both the compact growth cones and simple growth patterns along straight trajectories are suggestive of growth within fascicles of axons or radial glia (Lopresti et al., 1973; Tosney and Landmesser, 1985; Bovolenta and Mason, 1987; Kim et al., 1991; Williams et al., 1991; Halloran and Kalil, 1994; Brittis et al., 1995). Nevertheless, we did not directly observe labeled axons literally growing in contact with each other. There are at least two, nonexclusive reasons for this apparent discrepancy: (1) we deliberately labeled very few axons in each slice, so the probability of close neighbors being labeled was low; (2) our crystal placement was intended to label only thalamic axons. Therefore, the axons we studied may have been fasciculating with unlabeled fibers from other origins. Previous studies

Figure 7. Growth dynamics. The graph illustrates the contrasting behaviors of the main branch (blue, filled circles) and the side branch (red, open circles) of a thalamic axon in the VIZ. The panels at the bottom are single-frame confocal images collected at the times indicated by the solid lines. The lengths of the main axon (open arrow) and of the side branch (filled arrow) are measured from the stable bifurcation point at different times during a 70 min imaging session. Initially, most of the activity occurs in the side branch, which has branches of its own and appears to explore the surrounding territory. Gradually, the side branch becomes more quiescent and eventually retracts into the axon shaft; at the same time the main axon becomes “activated”: its growth cone becomes enlarged and it seems to take over the exploration. Scale bar, 10 μ m.

have suggested that thalamic fibers associate with several other axonal systems, which also could play a role in guiding them to their targets (McConnell et al., 1989; Ghosh et al., 1990; Ghosh and Shatz, 1992a; Mitrofanis and Baker, 1993; Mitrofanis and Guillery, 1993; Molnár and Blakemore, 1995; Métin and Godevent, 1996; Molnár et al., 1998) (see also Bicknese et al., 1994; Miller et al., 1995). The fact that not all axons in the IC manifest the tracking pattern further indicates that growth cones retain the ability to respond individually to pathfinding signals.

Ultimately, the growth patterns we observed have to be explained in molecular terms. The signaling factors that might be guiding thalamic axons through the striatum are beginning to be identified. At least two secreted proteins, netrin-1 and semaphorin E (semE), that are expressed in the developing striatum (Serafini et al., 1996; I. Skaliora, W. Singer, H. Betz, and A. Püschel, unpublished results) were found to attract axons from cortical explants (Métin et al., 1997; Richards et al., 1997; Bagnard et al., 1998). These or other guidance cues could have similar effects on thalamic axons.

Nonetheless, although such signals are probably important for establishing the *direction* of growth, they cannot by themselves

account for the axonal morphology and behavior that we observed. We can think of three possible ways to explain the small size, streamlined morphology, lack of branching, and signs of fasciculated growth. First, thalamic axons could be strongly attracted to other fibers that express growth-supporting molecules, such as the immunoglobulin/fibronectin type III adhesion molecules (Stoeckli and Landmesser, 1995). Second, growth cones could be responding to molecular components in the developing striatum that encourage them to adopt active elongation behavior and discourage them from branching (Llirbat and Godevent, 1999). Third, these features could indicate the presence of inhibitory signals. The strongest candidate among the molecules already shown to be expressed in this region is semaphorin D (semD) (Giger et al., 1996; Skaliora et al., 1998), which has been shown to repel several types of axons (including thalamic) in culture (Luo et al., 1993; Messersmith et al., 1995; Püschel et al., 1995; Bagnard et al., 1996, 1998; Varela-Echavarría et al., 1997; Polleux et al., 1998). Although *in vivo* semD does not appear to set up an absolute barrier, because thalamic fibers still succeed in entering and crossing the striatum, it may be acting as a partial repellent, allowing growth but preventing branching or synapse

Table 1. Qualitative characteristics of axonal behavior grouped by growth pattern and location

Axon	Sequence	Age	Growth pattern	Location	Duration	Sidebranch activity	Change in direction
1	1	E18	Tracking	IC	175	No	No
2	2	E18	Tracking	IC	260	No	No
3	3	E17	Tracking	IC	105	No	No

	28	E17	Elongation	VIZ→	75	No	No

“Sequence” refers to periods of observation, >30 min, which were characterized by a single type of behavior. Usually (in 22 of the 25 axons studied), one axon corresponds to one sequence; in the remaining three cases, in which there was evidence of transition in behavior, the entire observation period was divided in two nonoverlapping sequences that were classified separately. “Duration” indicates the time in minutes for which each particular sequence was studied. “Sidebranch activity” refers to the extension and/or retraction of filopodia and sidebranches along the distal 60 μ m portion of the axon. The “change in direction” is indicated by the degrees of shift in trajectory, as well as by whether there were single or multiple turns during the imaging session. In cases of multiple turns the angular measurement reflects the largest shift in direction. IC, Internal capsule; VIZ, ventral intermediate zone; IC→, indicates growth cone was located in the IC, but close to the border to the VIZ; →VIZ, indicates growth cone had just entered the VIZ; VIZ→, indicates growth cone was located at the dorsolateral border of the VIZ, about to exit the region outlined in Fig. 1, toward the overlying cortex.

Table 2. Quantification of axonal behavior in the two locations

		Net growth rate (μ m/hr)	Rate during advance (μ m/hr)	% Advance	% Pause	% Retraction
IC	Mean	17.26	55.01	79.40	12.86	7.73
	SD	4.44	29.67	10.54	5.25	7.37
VIZ	Mean	8.39	42.34	37.53	37.56	24.91
	SD	5.34	12.67	13.50	16.14	11.11

Net growth rate was calculated as the change in axon length over the total observation time, and rate during advance is the change in axon length during periods of advance only. The percentage of advance, pause, and retraction values indicates the percentage of consecutive 5 min intervals that the axons spent in advance, pause, and retraction, respectively (also see Materials and Methods). For the two axons that moved from the IC into the VIZ during the period of observation, these parameters were calculated separately for each location.

formation. Such functions have been demonstrated for semaphorins in different species (Matthes et al., 1995; Isbister et al., 1999) and are also reminiscent of retinal axons in culture that are inhibited from branching, but are not prevented from extending, on a substrate of caudal tectal membranes (Roskies and O’Leary, 1994). Interestingly, thalamic axons branch selectively within layer 4, the only cortical layer that does not express any of the semaphorin genes (Skalióra et al., 1998). Hence, semD could provide a surround repulsion that prevents branching and synapse formation in inappropriate regions. These three alternatives are

not mutually exclusive, and they would all be consistent with our findings.

Axon guidance in the ventral intermediate zone

The characteristic changes in the morphology and behavior we observed in this area are all hallmarks of axons reaching transition points in their paths, such as decision regions or entry into targets. For instance, in the optic chiasm, one of the better studied and unambiguous decision areas, growth cones tend to be large and complex, as axons go through protracted pauses and have

Figure 8. Example of “transition” behavior in an axon for which the leading segment is at the border between IC and VIZ, in a slice obtained from an E17 embryo. The panels at the top are single-frame confocal images of the growth cone. The data points in the graph illustrate the net advance of the axon during the period of observation. Scale bar, 10 μ m.

short periods of advance (Bovolenta and Mason, 1987; Godement et al., 1994; Mason and Wang, 1997; Chan et al., 1998). The duration of pauses differs between studies, ranging from 15 to 60 min (Sretavan and Reichardt, 1993; Chan et al., 1998) up to several hours (Godement et al., 1994). Also in the chiasm, axons are often observed to change their trajectory, usually by selective remodeling of different parts of the motile apparatus of the growth cone, immediately after a pause (Sretavan and Reichardt, 1993; Godement et al., 1994; Chan et al., 1998). Such behaviors have also been encountered in other transition points (Harris et al., 1987; Kaethner and Stuermer, 1992; Halloran and Kalil, 1994; Yamamoto et al., 1997) and are consistently similar to our findings of thalamic axons reaching the VIZ. Taken together, they suggest that axons in this area are responding individually to a new set of local cues and imply that the dorsolateral border of the differentiating basal ganglia constitutes a decision region for thalamic axons.

The molecular signals that trigger these responses are presently unknown. The changes in growth cone morphology and growth patterns occur over a fairly restricted region, arguing against a global diffusion gradient generated from cortical target regions. Instead they imply localized guidance cues—which are likely to include inhibitory factors, to account for the longer and more frequent pauses, but also attractive factors, to account for the expanded size and increased complexity of growth cones (Le-

tourneau, 1975, 1982; Caudy and Bentley, 1986a; Kuhn et al., 1995; Isbister and O'Connor, 1999). A localized increase in affinity could either provide direct guidance information to thalamic axons (Letourneau, 1975; Gundersen, 1985; Hammarback et al., 1985; O'Connor et al., 1990), or it may serve mainly to enlarge the surface area of their growth cones, thus increasing their potential to integrate spatially divergent signals (Isbister and O'Connor, 1999).

Finally, the pronounced pauses in this area could reflect cellular interactions and the formation of specialized membrane contacts between thalamic axons and other axonal or cellular elements, much like the behavior of retinal axons in the chiasm (Bovolenta and Mason, 1987; Marcus and Mason, 1995; Marcus et al., 1995; Colello and Coleman, 1997). Such contacts might trigger subsequent rearrangements of surface receptors that would contribute to the frequent changes in trajectory we observed in this region (Dodd et al., 1988; Seeger et al., 1993; Stoeckli and Landmesser, 1998).

Concluding remarks

Our results suggest that thalamic axons use other axons as a preferred substrate through the bulk of the striatum, although they appear to retain the ability to respond individually to the available cues. The findings also indicate that, as thalamic axons reach the border between basal and dorsal telencephalon, this

close association with other axons is no longer sufficient to carry them further, because axons go through repeated cycles of extension, pause, and retraction and extend filopodia in different directions before resuming forward advance, usually in a different direction. This suggests that growth cones are receiving and integrating a novel set of cues to make the next pathfinding decision. The molecular signals responsible for the observed behaviors are unknown but in all likelihood will consist of a combination of attractive and repulsive cues presented in a precise spatial and temporal arrangement. The experimental design and results presented in this study provide, for the first time, the basis for examining the separate and combined effects of such guidance cues in an accessible yet intact preparation of the thalamocortical pathway.
