We performed nonradioactive *in situ* hybridization histochemistry (ISH) in the lateral geniculate nucleus (LGN) of the macaque monkey to investigate the distribution of mRNA for two growth-associated proteins, GAP-43 and SCG10. GAP-43 and SCG10 mRNAs were coexpressed in most neurons of both magnocellular layers (layers I and II) and parvocellular layers (layers III–VI). Double-labeling using nonradioactive ISH and immunofluorescence revealed that both GAP-43 and SCG10 mRNAs were coexpressed with the α -subunit of type II calcium/calmodulin-dependent protein kinase, indicating that both mRNAs are expressed also in koniocellular neurons in the LGN. We also showed that GABA-immunoreactive neurons in the LGN did not contain GAP-43 and SCG10 mRNAs, indicating that neither GAP-43 nor SCG10 mRNAs were expressed in inhibitory interneurons in the LGN. GABA-immunoreactive neurons in the peri-

geniculate nucleus, however, contained both GAP-43 and SCG10 mRNAs, indicating that both mRNAs were expressed in inhibitory neurons in the perigeniculate nucleus, which project to relay neurons in the LGN. Furthermore, to determine whether the expression of GAP-43 and SCG10 mRNAs is regulated by visual input, we performed nonradioactive ISH in the LGN and the primary visual area of monkeys deprived of monocular visual input by intraocular injections of tetrodotoxin. Both mRNAs were downregulated in the LGN after monocular deprivation for 5 d or longer. From these results, we conclude that both GAP-43 and SCG10 mRNAs are expressed in the excitatory relay neurons of the monkey LGN in an activity-dependent manner.

Key words: GAP-43; SCG10; LGN; macaque monkey; growth-associated protein; koniocellular; GABA; monocular deprivation; *in situ* hybridization; activity-dependent regulation

During a critical period in the development of the monkey brain, monocular deprivation causes an expansion of geniculocortical axons receiving input from a normal eye and a contraction of geniculocortical axons receiving input from a deprived eye (LeVay et al., 1980). After the critical period, monocular deprivation does not cause such structural rearrangement of geniculocortical axons. Nevertheless, some physiological expansion of ocular dominance columns serving the normal eye of monocularly deprived adult monkeys is also reported, determined by single-unit recording (LeVay et al., 1980).

To investigate the basis for such a plastic response in the adult monkey geniculocortical system, we focused on the expression of two growth-associated proteins, GAP-43 and SCG10, in the lateral geniculate nucleus (LGN) and the primary visual area. GAP-43 is localized in nerve terminals of the neuropil (Nelson and Routtenberg, 1985; Meiri et al., 1986, 1988; Skene et al., 1986) and participates in signal transduction during axonal elongation and synaptic growth (Akers and Routtenberg, 1985; Alexander et al., 1987; Strittmatter et al., 1990). Another growth-associated protein, SCG10, also accumulates in nerve terminals (Stein et al., 1988a) and is thought to participate in axonal elongation and synaptic

growth (Stein et al., 1988b; McNeill et al., 1992; Hannan et al., 1996) by regulating the instability of microtubules (Riederer et al., 1997). GAP-43 and SCG10 are abundant in a developing nervous system and persist in certain regions of the adult nervous system such as the association areas of the cerebral cortex and the hippocampus, where structural or functional changes may continue to occur (Neve et al., 1988; Benowitz et al., 1989; Himi et al., 1994a,b; Sugiura and Mori, 1995; Higo et al., 1998, 1999a; Oishi et al., 1998). It is generally believed that these growth-associated proteins serve as an intrinsic determinant of synaptic growth and plasticity even in the adult brain (McNeill et al., 1992; Aigner et al., 1995; Holtmaat et al., 1995; Kapfhammer, 1997) (for review, see Benowitz and Routtenberg, 1997).

To understand the synaptic plasticity in the geniculocortical system by using GAP-43 and SCG10 as molecular markers, the first step is to determine the localization of GAP-43 and SCG10 mRNAs. Recently, we performed a nonradioactive *in situ* hybridization histochemistry (ISH) in the primary visual area and revealed that prominent hybridization signals for GAP-43 and SCG10 mRNAs are restricted to layers IV–VI (Higo et al., 1999a). In this study, we applied the same method to the monkey LGN, which includes three types of excitatory relay neurons (magnocellular, parvocellular, and koniocellular neurons), plus inhibitory interneurons (Hendry and Calkins, 1998).

The second step is to determine whether the expression of GAP-43 and SCG10 mRNAs in the geniculocortical system is regulated by the visual input. Thus, we performed a nonradioactive ISH in both the LGN and the primary visual area of monkeys deprived of monocular visual input by intraocular injections of tetrodotoxin (TTX). We found that both mRNAs were downregulated in the LGN but not in the primary visual area of monocularly deprived monkeys.

Preliminary results have been published previously (Higo et al., 1999b,c).

Received Nov. 22, 1999; revised June 1, 2000; accepted June 1, 2000.

This work was supported by grants from the Agency of Industrial Science and Technology, the Ministry of International Trade and Industry, Japan, and the Cooperation Research Program of the Primate Research Institute, Kyoto University. We are grateful to Dr. K. Kawano and Dr. T. Arikuni for their valuable discussions and continuous encouragement during this study. We thank Dr. R. L. Neve for providing the cDNA clone for GAP-43 and Dr. N. Mori for providing the cDNA clone for SCG10. We also thank M. Okui, T. Takasu, and A. Kameyama for their excellent technical assistance.

MATERIALS AND METHODS

Animals and tissue preparation. Brain tissue was obtained from 11 macaque monkeys (six *Macaca fuscata* and five *Macaca mulatta*) aged 2 or more years. Monkeys were purchased from a local provider or were bred in the Primate Research Institute, Kyoto University. To investigate the effect of visual deprivation on the expression of GAP-43 and SCG10 mRNAs, five monkeys received TTX (Sigma, St. Louis MO) (15 μ g in 10 μ l of normal saline), injected intravitreally into the right eye every fifth day for a total of 5 ($n = 2$), 10 ($n = 2$), and 30 ($n = 1$) d before they were killed. Monkeys were anesthetized with ketamine hydrochloride (10 mg/kg, i.m.) and pentobarbital sodium (Nembutal; 20 mg/kg, i.v.) before TTX administration. The pupillary light reflex of these monocularly deprived monkeys remained suppressed throughout the deprivation period.

All animals were pretreated with ketamine hydrochloride (10 mg/kg, i.m.), then deeply anesthetized with Nembutal (35 mg/kg, i.v.). Next, they were perfused through the ascending aorta with 0.5 l of ice-cold saline containing 2 ml (2000 U) of heparin sodium, followed by 2–5 l of ice-cold fixative: 4% paraformaldehyde (PFA) and 0.1% glutaraldehyde in 0.15 M phosphate buffer (PB), pH 7.4. During perfusion, the monkeys' heads were chilled with crushed ice. After perfusion, the brains were immediately removed and blocked in the coronal plane (5 mm thick). The occipital lobe was blocked in a plane parallel to the cortex. They were then immersed in a postfixative solution containing 2% PFA and 5% sucrose in 0.15 M PB for several hours, followed by successive immersions in 10, 20, and 30% sucrose in 0.15 M PB. The brain blocks were mounted in O.C.T. compound (Miles Inc., Elkhart, IN) and frozen rapidly in a dry ice/acetone bath, then stored at -80°C until dissection.

In situ hybridization. Digoxigenin-labeled RNA probes were used for the detection of GAP-43 and SCG10 mRNAs. RNA probes for GAP-43 and SCG10 were transcribed from human cDNA clones for GAP-43 (pG#20, 500 bp; a gift from Dr. R. L. Neve, Harvard Medical School, Boston) and SCG10 (pSG601, 550 bp; a gift from Dr. N. Mori, National Institute for Longevity Sciences, Oobu, Aichi, Japan), using an *in vitro* transcription method according to the manufacturer's instructions (DIG-RNA Labeling Kit, Boehringer Mannheim Biochemica, Mannheim, Germany). Before use, the labeled probes were precipitated with ethanol, then washed to remove unincorporated digoxigenin-labeled nucleotides.

Tissue blocks containing the LGN or the primary visual cortex were sliced into 16- μ m-sections on a cryostat (CRYOCUT 3000, Leica, Nussloch, Germany). The sections were mounted on slides coated with Vectabond Reagent (Vector Laboratories, Burlingame CA), dried, then pre-treated for ISH by successive incubations in 4% PFA in 0.1 M PB for 15 min at room temperature, 30 μ g/ml Proteinase K (Boehringer Mannheim Biochemica), pH 8.0, for 30 min at 37°C , and 4% PFA in 0.1 M PB for 10 min at room temperature. After washing with 0.1 M PB, the sections were dehydrated through 70, 80, 90, and 100% ethanol serial washes (1 min at each concentration) and then dried.

Sections were prehybridized in 50% formamide, 600 mM NaCl, 1 $\times$ Denhardt's solution, 0.25% SDS, 10 mM Tris-HCl, pH 7.6, 1 mM EDTA, and 200 μ g/ml tRNA for 3 hr at 50°C . After prehybridization, sections were transferred to fresh hybridization buffer containing an additional 10% dextran sulfate and 1 μ g/ml digoxigenin-labeled RNA probe. Hybridization continued for at least 16 hr at 50°C . The hybridized sections were rinsed three times in 5 $\times$ SSC at room temperature, then washed three times (10 min each) in preheated 2 $\times$ SSC, 50% formamide at 48°C . Next, sections were treated with 10 mM Tris-HCl, pH 7.5, 1 mM EDTA, 0.5 M NaCl containing RNase A (Boehringer Mannheim Biochemica; 30 μ g/ml) for 30 min at 37°C , then washed in 2 $\times$ SSC for 20 min at 50°C and twice in 0.2 $\times$ SSC at 50°C , for 20 min each time.

The buffer was changed to 0.1 M maleic acid, 0.15 M NaCl, and 0.2% Tween 20, pH 7.5, with a 10 min wash at room temperature. Sections were then incubated in 2% blocking reagent (DIG Nucleic Acid Detection Kit, Boehringer Mannheim Biochemica), 0.1 M maleic acid, and 0.15 M NaCl, pH 7.5, for 1 hr at room temperature, then incubated in 1:500 diluted anti-digoxigenin Fab-fragments conjugated with alkaline phosphatase (DIG Nucleic Acid Detection Kit, Boehringer Mannheim Biochemica) in 2% blocking reagent, 0.1 M maleic acid, and 0.15 M NaCl, pH 7.5, for 3 hr at room temperature. Unbound antibody conjugate was removed by washing three times for 10 min each with 0.1 M maleic acid, 0.15 M NaCl, and 0.2% Tween 20, pH 7.5. Finally, the sections were preincubated in 0.1 M Tris-HCl buffer, pH 9.5, containing 0.1 M NaCl and 0.05 M MgCl_2 for 5 min, then incubated for 20 hr in the dark in the same buffer containing the substrates: nitroblue tetrazolium (NBT) (340 μ g/ml; Boehringer Mannheim Biochemica) and 5-bromo-4-chloro-3-indolyl phosphate (BCIP, 170 μ g/ml) (Boehringer Mannheim Biochemica). Color development was stopped by incubation in 0.1 M Tris-HCl buffer, pH 7.5, containing 0.01 M EDTA for 10 min. The sections were incubated in 4% PFA in 0.15 M PB for 10 min at room temperature to prevent fading. After this, sections were dehydrated through 70, 80, 90, and 100% ethanol serial washes (1 min at each concentration), transferred to xylene for three washes of 5 min each, then covered with coverslips and Permount histological mounting medium (Fisher Scientific, Fair Lawn, NJ).

The specificity of the probes was confirmed by Northern blot analysis, in which specific bands for both GAP-43 and SCG10 mRNAs were observed, as in a previous study (Higo et al., 1998). In addition, control sections were hybridized using the same method described above, using the sense probes

for both mRNAs. These control sections showed no specific signals (see Fig. 1D,E).

Double-label ISH. To investigate whether GAP-43 and SCG10 mRNAs are coexpressed in the single neuron of the LGN, double-label ISH was performed. For this purpose, we synthesized a digoxigenin-labeled probe for GAP-43 mRNA and a biotin-labeled probe for SCG10 mRNA. To amplify the signals from the biotin-labeled probes, we used the tyramide signal amplification technique (TSA-indirect, NEN Life Science Products, Boston, MA).

The biotin-labeled probe was made using an *in vitro* transcription method according to the manufacturer's instructions (DIG-RNA Labeling Kit and Biotin RNA Labeling Mix, Boehringer Mannheim Biochemica). Before use, the labeled probes were precipitated with ethanol, then washed to remove unincorporated biotin-labeled nucleotides. The pretreatment, prehybridization, hybridization, and washing of the probes were performed in the same manner as described above, except the hybridization took place in the buffer containing both the digoxigenin-labeled probes for GAP-43 mRNA and the biotin-labeled probes for SCG10 mRNA. After the probes were washed, the buffer was changed to 0.1 M Tris-HCl, 0.15 M NaCl, and 0.05% Tween 20, pH 7.5, and the probes were incubated for 15 min at room temperature. Tissue sections were incubated in 0.5% blocking reagent (TSA-indirect, NEN Life Science Products), 0.1 M Tris-HCl, and 0.15 M NaCl, pH 7.5, for 1 hr at room temperature, then were incubated in 1:100 diluted streptavidin-HRP (TSA-indirect, NEN Life Science Products), 0.5% blocking reagent, 0.1 M Tris-HCl, and 0.15 M NaCl, pH 7.5, for 1 hr at room temperature. Unbound streptavidin-HRP was removed by washing three times for 5 min each with 0.1 M Tris-HCl, 0.15 M NaCl, and 0.05% Tween 20, pH 7.5. Sections were incubated in Biotinyl Tyramide Working Solution (TSA-indirect, NEN Life Science Products) for 20 min, then washed three times for 5 min each with 0.1 M Tris-HCl, 0.15 M NaCl, and 0.05% Tween 20, pH 7.5. Sections were then incubated in 1:100 diluted Streptavidin-Alexa488 (Molecular Probes, Eugene OR), 0.5% blocking reagent, 0.1 M Tris-HCl, and 0.15 M NaCl, pH 7.5, for 30 min at 48°C . After washing three times for 10 min each with 0.1 M Tris-HCl, 0.15 M NaCl, and 0.05% Tween 20, pH 7.5, the sections were covered with coverslips and a 0.1 M PBS/glycerol solution. Images were captured with a fluorescence microscope (BX60; Olympus, Tokyo, Japan) equipped with an illuminator (BX-FLA; Olympus), using a 3CCD color video camera (DXC-950; Sony, Tokyo, Japan). Next, the sections were incubated in 0.1 M maleic acid, 0.15 M NaCl, and 0.2% Tween 20, pH 7.5, to remove the coverslips, and digoxigenin-labeled probes for GAP-43 were visualized with NBT and BCIP by the same methods described above.

To evaluate the specificities of the biotin-labeled probes for SCG10 mRNA, control sections were hybridized using the same method described above, using the sense probe. These control sections showed no specific signals (data not shown).

Double-labeling using ISH and immunofluorescence. To investigate whether GAP-43 and SCG10 mRNAs are coexpressed with the α -subunit of type II calcium/calmodulin-dependent protein kinase (CAMKII- α) or GABA in the LGN of normal monkeys, we conducted double-labeling experiments using nonradioactive ISH and immunofluorescence. We performed immunofluorescence first, capturing the immunofluorescent image, and then performed nonradioactive ISH.

The sections were rinsed three times in 0.1 M PBS, pH 7.4, and preincubated in 1% BSA, 0.02% sodium azide, and 0.6% Triton X-100 in PBS for 4 hr at room temperature. Sections were then incubated for 60 hr at 4°C in the primary antibodies, a mouse monoclonal antibody to CAMKII- α (6G9; Biomol Research Laboratories, Plymouth Meeting, PA) diluted 1:100 in 0.1 M PBS containing 1% BSA, 0.02% sodium azide, and 0.3% Triton X-100, or a mouse monoclonal antibody to GABA (GB69; Sigma) diluted 1:800 in the same buffer. After washing three times for 15 min each with 0.1 M PBS, the sections were incubated for 12 hr at room temperature in the secondary antibody, Alexa 488 goat anti-mouse IgG (H+L) conjugate (Molecular Probes) diluted 1:400 in 0.1 M PBS containing 1% BSA, 0.02% sodium azide, and 0.3% Triton X-100. After washing three times for 15 min each with 0.1 M PBS, the sections were covered with coverslips and a 0.1 M PBS/glycerol solution. Images were captured with a fluorescence microscope (BX60; Olympus) equipped with an illuminator (BX-FLA; Olympus), using a 3CCD color video camera (DXC-950; Sony). The sections were incubated in 0.1 M PBS to remove the coverslips, then were hybridized with the digoxigenin-labeled probes of GAP-43 or SCG10, as described above.

The specificity of each primary antibody was confirmed in previous studies (Kalyuzhny and Wessendorf, 1998; Tanigawa et al., 1998; Tighilet et al., 1998a,b). Control sections were processed using the same method described above, except the primary antibodies were excluded. These control sections showed no specific signals (data not shown).

Quantification. To quantify the expression patterns in the LGN and the primary visual area of monocularly deprived monkeys, images of *in situ* hybridized sections or adjacent Nissl- or cytochrome oxidase-stained sections were captured with an Olympus BX60 microscope using a 3CCD color video camera (DXC-950; Sony). The images were then digitized with an image analysis system (MCID; Imaging Research Inc., St. Catharines, Canada).

In the LGN, optical density was measured in each layer of a 300- μ m-wide column that sampled from layer I to layer VI, and the optical density of the background staining was measured in the neighboring cell-free

regions. OD(%Background) was defined as a percentage of optical density to that of the background staining (see Figs. 4C, D, G, H, 5C, D, G, H). The layers of *in situ* hybridized sections were identified by adjacent Nissl-stained sections.

In the primary visual area, we showed the relative optical density in each section in pseudocolor representation. The resolutions of the digitized images were reduced from $1.03 \times 10^2 \text{ mm}^2/4096 \times 4096$ pixels to $2.52 \times 10^3 \text{ mm}^2/4096 \times 4096$ pixels, and the optical density was measured in each pixel. Using MATLAB version 5.0.0 (The Math Works Inc., Natick, MA) on a Power Macintosh G3 (Apple Computer, Inc., Cupertino, CA), the optical density in each pixel was plotted in pseudocolor representation (see Fig. 8B, D, F, H).

RESULTS

Expression of GAP-43 and SCG10 mRNAs in normal LGN

In normal LGN, expression of both GAP-43 and SCG10 mRNAs was observed in the neurons of all layers (Fig. 1B, C). The hybridization signals for SCG10 mRNA were more intense than those for GAP-43 mRNA. Weak signals for GAP-43 mRNA and intense signals for SCG10 mRNA were also observed in the perigeniculate nucleus (Fig. 1B, C). These results were similar among all animals examined ($n = 6$) and throughout the rostral to caudal levels of the coronal sections. Higher-magnification photomicrographs revealed that many GAP-43 mRNA- or SCG10 mRNA-positive neurons existed in magnocellular layers (layers I and II), in parvocellular layers (layers III–VI), and in interlaminar regions (Fig. 1G, H). These neurons varied in size (10–30 μm in diameter), and were oval, triangular, or rectangular in shape. Double-label ISH study revealed that GAP-43 and SCG10 mRNAs colocalized in most LGN neurons (Fig. 2). Signals were selective for GAP-43 mRNA (Fig. 2A, C, arrows) or SCG10 mRNA (Fig. 2B, C, arrowheads) in some LGN neurons.

Recent studies revealed that there is a third population of neurons in the primate LGN, in addition to the magnocellular and parvocellular neurons, known as koniocellular neurons. A subset of koniocellular neurons relay excitatory input from short-wavelength-sensitive cones in the retina (Martin et al., 1997; Reid et al., 1997; for review, see Komatsu, 1998) and send retinal signals directly to the blobs of the primary visual area of the cerebral cortex (Hendry and Yoshioka, 1994; Hendry and Calkins, 1998). To investigate whether GAP-43 and SCG10 mRNAs are expressed in koniocellular neurons as well as in magnocellular and parvocellular neurons, we used a double-labeling technique involving non-radioactive ISH of GAP-43 and SCG10 mRNA and immunofluorescence of CAMKII- α , a molecular marker of koniocellular neurons (Hendry and Yoshioka, 1994; Hendry and Calkins, 1998). Most CAMKII- α -immunoreactive neurons were observed in regions ventral to each of six layers as reported previously (Hendry and Yoshioka, 1994; Hendry and Calkins, 1998) and were relatively small in size (10–20 μm in diameter) and round in shape (Fig. 3B, E). Our double-labeling experiments confirmed that nearly all CAMKII- α -positive neurons expressed mRNAs of GAP-43 and SCG10 (Fig. 3A–F), indicating that koniocellular neurons as well as magnocellular and parvocellular neurons contain GAP-43 and SCG10 mRNAs.

We also conducted double-labeling experiments involving non-radioactive ISH of GAP-43 and SCG10 mRNA and immunofluorescence of GABA. In the LGN, GABA-immunoreactive neurons were observed in both magnocellular and parvocellular layers and varied in size (10–30 μm in diameter) and shape (Fig. 3H, K), as reported previously (Montero and Zempel, 1986). The double-labeling experiments confirmed that GAP-43 and SCG10 mRNAs were not expressed in GABA-immunoreactive neurons (Fig. 3G–L). Previous studies confirmed that GABA is expressed in inhibitory interneurons in the LGN (Fitzpatrick et al., 1984; Montero and Zempel, 1985; Montero and Zempel, 1986). Thus, the results of the present study indicate that GAP-43 and SCG10 mRNAs are not expressed in inhibitory interneurons. Some of the GAP-43 or SCG10 mRNA-positive neurons were outlined by GABA-immunoreactive terminals (Fig. 3G–L, arrows).

In the perigeniculate nucleus, nearly all neurons were GABA-

ergic (Fig. 3N, Q), consistent with previous studies (Hendrickson et al., 1983; Hendry, 1991), and most of them were fusiform in shape (20–50 μm in length). GABAergic neurons in the perigeniculate nucleus contained both GAP-43 and SCG10 mRNAs (Fig. 3M–R).

Effect of monocular deprivation

Figure 4 shows the effects of monocular deprivation in the LGN ipsilateral to the TTX-injected eye. The level of staining for cytochrome oxidase was lower in layers II, III, and V than layers I, IV, and VI (Fig. 4B, D). This indicates that neuronal activity was reduced in these layers, as the result of visual deprivation of the ipsilateral eye. The amount of both GAP-43 and SCG10 mRNAs was also lower in layers II, III, and V than in layers I, IV, and VI (Fig. 4E–H), indicating that both GAP-43 and SCG10 mRNAs were downregulated in the layers deprived of visual input. In the adjacent Nissl-stained section, however, the apparent reduction of staining was not observed (Fig. 4A, C), indicating that cell shrinkage did not occur in the deprived layers. In the LGN contralateral to the TTX-injected eye, just the opposite was observed. The levels of staining for cytochrome oxidase and of GAP-43 and SCG10 mRNAs were lower in layers I, IV, and VI than layers II, III, and V, although the apparent reduction of staining was not observed in the Nissl-stained section (Fig. 5). These results further confirmed that layers deprived of visual activity display lower levels of hybridization signals for both GAP-43 and SCG10 mRNAs than those of normally active layers. In the deprived layers, the hybridization signals for both GAP-43 and SCG10 mRNAs were reduced in nearly all neurons (Fig. 6). The signals were downregulated in all monocularly deprived monkeys regardless of the length of the deprivation period: 5 d ($n = 2$), 10 d ($n = 2$), or 30 d ($n = 1$) (Fig. 7). These results were similar throughout the rostral to caudal levels of the coronal sections. In the perigeniculate nucleus, the expression of both GAP-43 and SCG10 mRNAs was retained even after monocular deprivation for each period.

After monocular deprivation for 5, 10, or 30 d, we observed a periodic pattern of staining for cytochrome oxidase, especially in layer IVC of the primary visual area of the cerebral cortex (Fig. 8C, D), indicating that neuronal activity of ocular dominance columns that received visual input from the TTX-injected eye was reduced. However, we did not detect such a periodic ocular dominance pattern of staining for GAP-43 and SCG10 mRNAs after monocular deprivation for each period (Fig. 8E–H). Slight unequal distributions of both GAP-43 and SCG10 mRNAs in layer IVC correlated with the cell density revealed by the Nissl-stained section (Fig. 8A, B). The hybridization patterns for both GAP-43 and SCG10 mRNAs were nearly identical to those we had previously reported for normal monkeys (Higo et al., 1999a). These results indicate that in the primary visual area, the expression of GAP-43 and SCG10 mRNAs is not affected after monocular deprivation for these periods.

DISCUSSION

Expression of GAP-43 and SCG10 in the visual system of monkey

The present study showed that mRNAs of GAP-43 and SCG10, presynaptic determinants of synaptic growth and plasticity, were expressed in most neurons of the magnocellular, parvocellular, and koniocellular layers in the LGN. The expression of GAP-43 and SCG10 proteins is likely to be regulated by mRNA stability (Federoff et al., 1988; Perrone-Bizzozero et al., 1993; Nishizawa, 1994; Hannan et al., 1996), and several *in vivo* studies confirmed that the expression of GAP-43 and SCG10 mRNAs in the neuronal cell body is correlated with the expression of GAP-43 and SCG10 proteins in the axon terminals (Van der Zee et al., 1989; Tetzlaff et al., 1991; Linda et al., 1992; Chong et al., 1994; Bendotti et al., 1997; McNeill et al., 1999). Neurons in the koniocellular layer project to both the blobs of the primary visual area (Hendry and Yoshioka, 1994; Hendry and Calkins, 1998) and the prestriate area (Ben-evento and Yoshida, 1981; Fries, 1981; Yukie and Iwai, 1981; Bullier and Kennedy, 1983; Lysakowski et al., 1988), indicating that

Figure 1. *A–E*, Five adjacent sections of the normal LGN. Expression of both GAP-43 and SCG10 mRNAs was observed in the neurons of all layers. The expression patterns of both GAP-43 and SCG10 mRNAs were similar among all animals examined and throughout the rostral to caudal levels of the coronal sections. *A*, Nissl-stained section. *B*, Localization of GAP-43 mRNA. *C*, Localization of SCG10 mRNA. *D*, Control section hybridized with a sense probe for GAP-43. *E*, Control section hybridized with a sense probe for SCG10. *Prg*, Perigeniculate nucleus. Scale bar, 1 mm. *F–H*,

Figure 2. Coexpression of GAP-43 and SCG10 mRNAs in layers II and III of the LGN. *A*, Localization of GAP-43 mRNA. *B*, Localization of SCG10 mRNA in the same section as *A*. *C*, The image of *B* was superimposed on the image of *A*. Most of the neurons contained the hybridization signals for both GAP-43 mRNA (dark blue) and SCG10 mRNA (green). In some neurons, the signal was selective for GAP-43 mRNA (arrows) or SCG10 mRNA (arrowheads). Scale bar, 100 μ m.

GAP-43 and SCG10 exist in the axon terminals of these projections. Neither the GAP-43 nor SCG10 mRNA-positive neurons in both magnocellular and parvocellular layers contained GABA, indicating that GAP-43 and SCG10 mRNAs were expressed in most of the excitatory relay neurons in these layers. Excitatory relay neurons in the magnocellular and parvocellular layers of the LGN project to layers IVC α and IVC β of the primary visual area, respectively (Wilson and Cragg, 1967; Garey and Powell, 1971; Hubel and Wiesel, 1972; Hendrickson et al., 1978). Thus GAP-43 and SCG10 should exist in the geniculocortical axon terminals in the primary visual area. The result is consistent with the previous study showing that GAP-43 protein is localized in the neuropil around neurons in layer IV of the cat primary visual area (Liu et al., 1996). In the LGN, the expression of both GAP-43 and SCG10 mRNAs was downregulated after monocular deprivation for 5 d or longer. Because *in vivo* studies confirmed that the downregulation of GAP-43 and SCG10 mRNAs is followed by the downregulation of GAP-43 and SCG10 proteins (Van der Zee et al., 1989; McNeill et al., 1999), the downregulation of GAP-43 and SCG10 mRNA in relay neurons of the LGN should result in the downregulation of GAP-43 and SCG10 proteins in the geniculocortical axon terminals.

In the primary visual area of both normal and monocularly deprived monkeys, prominent hybridization signals for both GAP-43 and SCG10 mRNAs were observed in layers IV–VI (Higo et al., 1999a; present study). Intense signals were frequently observed in Meynert cells in layers IVB, V, and VI, which project to area MT of the cortex or the superior colliculus (Lund and Boothe, 1975; Tigges et al., 1981; Fries and Distel, 1983; Sipp and Zeki, 1989; Peters, 1994). In contrast to the result in the LGN, the expression of GAP-43 and SCG10 mRNAs in the primary visual area was not affected by monocular deprivation. The lack of effect on the expression of GAP-43 mRNA in the primary visual area is consistent with the previous study showing that dark rearing after

Higher-magnification photomicrographs showing downregulation of hybridization signals for GAP-43 mRNA (*A*, *C*) and SCG10 mRNA (*B*, *D*) after 10 d of monocular deprivation. *A*, *B*, Layers I–IV of the LGN ipsilateral to the TTX-injected eye. The photomicrographs were taken from the same section as in Figure 4. *C*, *D*, Layers I–IV of the LGN contralateral to the TTX-injected eye. The photomicrographs were taken from the same section as in Figure 5. Scale bar, 100 μm.

a critical period does not cause an alteration of GAP-43 mRNA levels in the cat primary visual area, although it results in a significant alteration of GAP-43 mRNA levels during early postnatal life (Mower and Rosen, 1993).

Relationship to synaptic modifications in the visual system of the adult monkey

During a critical period in the development of the visual system, the geniculocortical axons are supposed to compete with one an-

Figure 7. OD(%Background) from each layer of the LGN hybridized for GAP-43 mRNA (*A, C*) and SCG10 mRNA (*B, D*). *A, B*, The LGN ipsilateral to the TTX-injected eye. *C, D*, The LGN contralateral to the TTX-injected eye. The hybridization signals for both GAP-43 and SCG10 mRNAs were reduced in the deprived layers (layers II, III, and V of the ipsilateral LGN and layers I, IV, and VI of the contralateral LGN) of all monocularly deprived monkeys regardless of the length of the deprivation period: 5 d (diamond and square), 10 d (triangle and circle), or 30 d (plus sign). OD(%Background) was measured from a 300- μ m-wide column sampling each layer of the LGN. Bars indicate the average of five monkeys.

other for neurotrophins in layer IV of the primary visual area (Thoenen, 1995; Bonhoeffer, 1996; McAllister et al., 1999). Among neurotrophins, mRNA of brain-derived neurotrophic factor (BDNF) persists in layer IV of the adult primary visual area of cat, and the expression is downregulated after monocular deprivation for 2 d (Lein and Shatz, 2000). Moreover, TrkB, the putative receptor for BDNF, is likely to exist in adult geniculocortical axons (Berardi and Maffei, 1999). Expression of both GAP-43 and SCG10 mRNAs is induced by BDNF (Fournier et al., 1997; Kobayashi et al., 1997; Imamura et al., 1999). Thus, the activity-dependent expression of GAP-43 and SCG10 mRNAs in the adult LGN may be caused by the activity-dependent expression of BDNF in layer IV of the adult primary visual area.

Several lines of evidence relate the expression of mRNAs of the growth-associated proteins GAP-43 and SCG10 with structural synaptic reorganization in the adult nervous system (Van der Zee et al., 1989; Tetzlaff et al., 1991; Linda et al., 1992; Levin and Dunn-Meynell, 1993; Chong et al., 1994; Aigner et al., 1995; Holtmaat et al., 1995; Bendotti et al., 1997; McNeill et al., 1999). Therefore, the activity-dependent expression of GAP-43 and SCG10 mRNAs in the adult LGN suggests that the activity-dependent plastic changes, such as proliferations or morphological alterations of synapses, occur in the geniculocortical axons of the adult monkey, even after geniculocortical axons lose the ability to extensively rearrange their terminals. Activity-dependent competition among geniculocortical synapses may account for some physiological expansion of ocular dominance columns serving the normal eye of the monocularly deprived monkey, as measured by single-unit recording [monkey no. 150 of LeVay et al. (1980)].

Figure 8. Surface parallel sections through the primary visual area (area 17 of Brodmann) of a monkey that has been monocularly deprived for 30 d (*A, C, E, G*). The relative optical densities in each section were also shown in pseudocolor representation (*B, D, F, H*). *A, B*, Nissl-stained section. *C, D*, Cytochrome oxidase-stained section. *E, F*, Localization of GAP-43 mRNA. *G, H*, Localization of SCG10 mRNA. The same blood vessels are indicated by arrows. No deprivation effect was observed for either GAP-43 or SCG10 mRNAs. Scale bar, 500 μ m.

A previous study showed that MAP-2 immunostaining is reduced in ocular dominance columns of layer IVC serving the TTX-injected eye of monocularly deprived monkeys (Hendry and Bhandari, 1992). The result suggests that reorganization of microtubules occurs in the dendrites or dendritic spines of geniculocortical recipient neurons. Moreover, the α -subunit of CAMKII is upregulated and the β -subunit of CAMKII is downregulated in the deprived ocular dominance column of layer IVC (Hendry and Kennedy, 1986; Benson et al., 1991; Tighilet et al., 1998a). Because CAMKII subserves an important part of protein kinase

C-associated synaptic plasticity at postsynaptic density (Liu and Jones, 1996; Wu and Cline, 1998; Chakravarthy et al., 1999), the result further supports the idea that the geniculocortical synapses of the adult monkey still have some types of activity-dependent plasticity. The present results may provide presynaptic mechanisms of the plastic changes of the adult geniculocortical synapses.

A growing body of evidence indicates that the structural changes of subcortical structures contribute to reorganization of the somatosensory body map (for review, see Kaas et al., 1999). The present result suggests that subcortical structures of the adult brain have a role in plasticity not only in the somatosensory pathway but also in the visual pathway.

A comparison with GABAergic system

We showed that GAP-43 and SCG10 mRNAs were not expressed in GABAergic neurons in the LGN. In the perigeniculate nucleus, however, GABAergic neurons contained both GAP-43 and SCG10 mRNAs. GABAergic neurons in the LGN are interneurons (Fitzpatrick et al., 1984; Montero and Zempel, 1985, 1986), whereas GABAergic neurons in the perigeniculate nucleus have projections to relay neurons in the LGN (Cucchiario et al., 1991; Uhlrich et al., 1991). Thus GAP-43 and SCG10 mRNAs are expressed in projection neurons of the monkey geniculate complex.

When monocular visual input is deprived in adult monkeys, GABA- and glutamate decarboxylase (GAD)-immunoreactive cell bodies and processes are decreased in layers of the LGN deprived of visual activity (Hendry, 1991). Deprivation periods of 3 weeks, however, are required to reduce the immunoreactivities of GABA and GAD (Hendry, 1991). The present results showed that both GAP-43 and SCG10 mRNAs were downregulated after monocular deprivation for periods of 5 d. The relatively rapid downregulation of GAP-43 and SCG10 mRNAs is similar to that of GABA_A receptor subunits, which are downregulated after monocular deprivation for periods of 4 d (Huntsman et al., 1995; Hendry and Miller, 1996). GABA_A receptor subunits (Hendry and Miller, 1996), as well as GAP-43 and SCG10 mRNAs, are expressed in relay neurons of the LGN. This suggests that the relatively rapid changes occur in the expression of molecules in relay neurons but that such changes are delayed in the inhibitory interneurons of the LGN.

In the perigeniculate nucleus, the expression of both GAP-43 and SCG10 mRNAs was retained even after monocular deprivation for each period. This is consistent with the studies of GABA and GAD immunoreactivities in the perigeniculate nucleus of monocularly deprived monkeys, which are identical to the immunoreactivities found in normal monkeys (Hendry, 1991). A previous study in cats reported that perigeniculate neurons typically are binocular (Xue et al., 1988). Thus, the present results indicate that monocular visual input may be sufficient for expressing both GAP-43 and SCG10 mRNAs as well as expressing GABA and GAD.
