The prevalence of smoking in human alcoholics is substantially higher than in the general population, and results from twin studies suggest that a shared genetic vulnerability underlies alcohol and nicotine addiction. Here, we directly tested this hypothesis by examining nicotine-taking behavior in alcohol-naive offspring of alcohol-preferring (P) rats and alcohol-nonpreferring (NP) rats that had been selectively bred for high and low alcohol intake. The self-administration of intravenous nicotine (0.015–0.060 mg/kg per infusion) in P rats was more than twice that of NP rats. Nicotine seeking induced by reexposure to nicotine cues in extinction tests was also substantially greater in P rats than in NP rats. In a subsequent relapse test, priming nicotine injections reinstated drug seeking in P rats but not NP rats. P rats also self-administered higher amounts of oral sucrose (1–20%) than NP rats, a finding consistent with previous reports. In contrast, self-administration of intravenous cocaine (0.1875–1.125 mg/kg per infusion) was remarkably similar in the P and NP rats; however, P–NP differences in cocaine seeking emerged in subsequent extinction and cocaine priming-induced reinstatement tests. In both cases, lever responding was higher in P rats than in NP rats. Thus, alcohol-naive offspring of rats genetically selected for high alcohol intake are highly susceptible to nicotine self-administration and relapse, and this susceptibility is not likely caused by general reward deficits in NP rats. The present findings provide experimental evidence for the hypothesis that a shared genetic determinant accounts for the co-abuse of nicotine and alcohol.

Key words: extinction; genetic vulnerability; nicotine self-administration; P rats; NP rats; reinstatement; relapse

Introduction

Alcohol and nicotine are the two most frequently used drugs in the world, and they are often used together (Kandel et al., 1997). In humans, high correlations have been found between alcohol and nicotine use: the prevalence of smoking in alcoholics is approximately three times higher than in the general population (Istvan and Matarazzo, 1984; Kandel et al., 1997). Results from studies using laboratory rats are in agreement with these correlational data in humans (Soderpalm et al., 2000). For example, repeated treatment with nicotine increases home-cage intake and operant self-administration of alcohol (Lê et al., 2000; Olausson et al., 2001), and nicotine injections reinstate alcohol seeking in a rat model of relapse to drugs (Lê et al., 2003); however, although nicotine can potentiate alcohol-taking behavior, no studies have been published regarding the effect of alcohol exposure on nicotine-taking behavior.

Genetic factors are known to contribute to alcohol and nicotine use in humans (Tyndale, 2003). Twin studies have shown substantial genetic influences (>50%) on both alcohol and nicotine addiction (Carmelli et al., 1992; Enoch and Goldman, 2001). Twin studies have also indicated that genetic factors may account for the co-abuse of nicotine and alcohol (Swan et al., 1997; Bierut et al., 2004; Goldman et al., 2005). For example, True et al. (1999) reported that the best-fitting model for the lifetime co-occurrence of nicotine and alcohol addiction includes a substantial genetic correlation between these disorders ($r = 0.68$). Results from studies using selective breeding of rats or mice for different effects of alcohol also demonstrate a substantial overlap between sensitivity to alcohol and sensitivity to nicotine. For example, mice or rats bred for increased responsiveness to the sedative effects of alcohol demonstrate increased sensitivities to nicotine-induced hypothermia and hypoactivity (De Fiebre et al., 1987). In another study, Gordon et al. (1993) examined alcohol-preferring (P) rats and alcohol-nonpreferring (NP) rats that were selectively bred for alcohol preference (Li et al., 1993) and reported that the P rats were more sensitive to nicotine than the NP rats in a drug discrimination procedure.

The studies reviewed above and other similar reports have led to the hypothesis that shared genetic factors mediate the co-abuse

of nicotine and alcohol (Tyndale, 2003); however, findings from human genetic studies are inconclusive, because comorbidity is common in many psychiatric disorders (Goldman et al., 2005; Krishnan, 2005) and because of the possibility that alcohol use leads to nicotine use or vice versa (Tyndale, 2003). Therefore, in our experiments, we tested the hypothesis that a shared genetic factor mediates vulnerability to both nicotine and alcohol by examining nicotine-taking behavior in alcohol-naïve offspring of P and NP rats. We found that the P rats self-administered greater amounts of nicotine intravenously and demonstrated substantially more robust nicotine seeking induced by reexposure to cues associated with nicotine or to nicotine itself, as measured in extinction and drug priming-induced reinstatement tests.

Materials and Methods

Subjects

Fifteen male P rats and 15 male NP rats (30–45 d old) from the 44th generation (lines iP-10A and iNP-4) and 11 male P rats and 11 male NP rats (65–92 d old) from the 46th generation of the same lines were purchased from Indiana University Medical Center (Indianapolis, IN). The rats were quarantined for 2–6 weeks before the start of the experiments and were housed singly under a 12 h light/dark cycle (lights on at 7:00 A.M.). Water was available *ad libitum* throughout the experiment except for 1 d before training for sucrose self-administration. Food (Purina Rat Chow) was available *ad libitum* until the onset of drug self-administration training. Subsequently, the rats were maintained on a restricted feeding of 20–22 g/d; food was given 1–2 h after the daily sessions. The experimental procedures followed the *Principles of Laboratory Animal Care* (NIH publication 85-23; 1996) and were approved by the local animal care committee.

Surgery

The rats were anesthetized with sodium pentobarbital (55 mg/kg, i.p.) and prepared surgically with SILASTIC catheters in the right jugular vein, as described previously (Corrigall and Coen, 1989). The catheter exited between the scapulas and was connected to a modified 22 gauge cannula. The rats were given an antibiotic treatment (Penlong, 30,000 U, i.m.; Rogar/STP, London, Ontario, Canada) immediately after surgery and were allowed 6–7 d to recover. The catheters were flushed daily with 0.1 ml of a saline–heparin solution (30 U/ml).

Apparatus

Nicotine and cocaine self-administration were performed in eight chambers that were operated by a Med Associates (St. Albans, VT) interface system. Each chamber had two levers located 10 cm above the floor, but only one, the active lever (a retractable lever), activated the infusion pump (Razel Scientific Instruments, Stamford, CT) for 0.5 s; presses on the inactive stationary lever were also recorded. The chambers were also equipped with a red house light and a white cue light that was located above the active lever. The modified 22 gauge cannula, attached to the intravenous catheter between the scapulas, was connected to fluid swivels (Lomir, Notre-Dame-de-L'Île Perrot, Quebec, Canada) with PE-50 tubing that was protected by metal springs. The swivels were connected to 10 ml syringes attached to the infusion pumps.

Sucrose self-administration was conducted in a set of 16 operant conditioning boxes that were constructed locally. Each chamber was equipped with two stationary levers, which were symmetrically centered on one side panel 5 cm above the floor, a house light, and a cue light. A response on the active lever activated the infusion pump and turned on the cue light for 5 s. Activation of the pump led to the delivery of 0.19 ml of the sucrose solution to a liquid drop receptacle. Presses on the inactive lever had no programmed consequences.

Drugs

Cocaine (BDH Chemicals, Oakville, Ontario, Canada) and nicotine (Sigma, St. Louis, MO) solutions were prepared fresh daily with sterile saline vehicle (the pH was adjusted to 7.0 for the nicotine solutions). The unit doses for the intravenous nicotine self-administration (infusion volume of 25 μ l over 0.5 s) were 0.015, 0.03, and 0.06 mg/kg per infusion (all

doses are expressed as the free base). Nicotine was also injected subcutaneously (0.15 mg/kg; injection volume, 1 ml/kg) during the tests for reinstatement. The unit doses for intravenous cocaine self-administration were 0.1875, 0.375, 0.75, and 1.125 mg/kg per infusion. During reinstatement testing, cocaine (5 and 10 mg/kg, i.p.) was injected in volume of 1 ml/kg. The nicotine and cocaine doses for self-administration and reinstatement are based on previous work (Corrigall and Coen, 1989; Shaham et al., 1997; Shoaib et al., 1997; Roberts and Brebner, 2000; Lu et al., 2004b).

Procedures

Experiment 1: Sucrose self-administration. The P and NP rats that subsequently underwent intravenous catheter surgery and were trained for intravenous nicotine and cocaine self-administration were initially trained to lever press for oral sucrose. In Experiment 1a, two groups of P and NP rats ($n = 15$ per line) were deprived of water for 24 h and then trained for 10 d (2 h/d for the first 3 d and 1 h/d for the last 6 d) to press a lever for 10% oral sucrose [0.19 ml per reward delivery; fixed ratio-1 (FR-1) schedule; each lever press was reinforced]. We found P–NP differences for the intake of 10% oral sucrose. Therefore, in Experiment 1b, two other groups of P and NP rats ($n = 11$ per line) were deprived of water for 24 h and then trained for 10 d (1 h/d) to press a lever for 10% oral sucrose. Subsequently we determined lever responding for different sucrose concentrations (1, 3, and 20%) in three counterbalanced sessions that were performed 3 d apart; the rats lever pressed for 10% sucrose during the intervening daily sessions.

Experiment 2: Nicotine self-administration, extinction, and reinstatement. The nicotine self-administration procedure was based on previous reports (Corrigall and Coen, 1989; Buczek et al., 1999). Initially, the rats were trained to self-administer nicotine (0.03 mg/kg per infusion) for 1 h/d for 24 d. At the start of the sessions, the red house light was turned on, the retractable lever was extended, and the white cue light above the retractable lever was illuminated for 30 s. Each nicotine infusion was accompanied by a 40 s time-out, during which responses were recorded but did not lead to drug delivery; during the time-out period, the cue light was illuminated. During days 1–10, active lever responding was reinforced under an FR-1 schedule; during days 11–16 and 17–24, responding was reinforced under FR-2 and FR-5 schedules, respectively. After the 24th session, a nicotine dose–response curve was determined during sessions 25–33 under an FR-5 schedule. The order in which the doses were presented was 0.060, 0.030, and 0.015 mg/kg per infusion, and the rats were given three sessions at each dose. The data from 9 of the 30 rats were excluded because of loss of catheter patency during training. The conditions during the 1 h extinction sessions were the same as during the training phase, except that lever responding under the FR-5 schedule led to the delivery of saline infusions. The saline infusions were accompanied by the illumination of the cue light that was previously paired with nicotine infusions for 40 s. The rats were given 7–23 extinction sessions until they reached an extinction criterion of fewer than 15 presses on the active lever per 1 h. During the extinction phase, the rats were injected at least three times with subcutaneous saline 30 min before the sessions to habituate them to the injection procedure. The extinction session during which the rats reached the extinction criterion after the subcutaneous saline injection served as a baseline against which the effect of nicotine priming injections on reinstatement was compared. On the next day, the effect of a priming injection of nicotine (0.15 mg/kg, s.c.; 30 min pretreatment time) on the reinstatement of nicotine seeking was examined. We chose the subcutaneous route because we and others have found that the priming effect of subcutaneous nicotine is more robust (and reproducible) than that of intravenous nicotine (Shaham et al., 1997; Andreoli et al., 2003; LeSage et al., 2004).

Experiment 3: Cocaine self-administration, extinction, and reinstatement. Cocaine self-administration was conducted in a manner similar to that described in Experiment 2 for nicotine. The rats ($n = 11$ per line) were trained to self-administer cocaine (0.75 mg/kg per infusion) for 1 h/d. During days 1–7, active lever responding was reinforced under an FR-1 schedule; during days 8–9 and 10–14, responding was reinforced under FR-2 and FR-5 schedules, respectively. Subsequently, a cocaine dose–response curve was determined under an FR-5 schedule. The dif-

ferent doses were given in the following order: 0.375, 0.75, 1.125, 0.75, and 0.1875 mg/kg per infusion, each for 2 d. The data from 2 of the 22 rats were excluded because of loss of catheter patency during training.

The extinction of lever responding for cocaine was performed in a manner similar to that described in Experiment 2 for nicotine, but for a longer time period. The rats were given 14–31 extinction sessions until they reached an extinction criterion of fewer than 15 presses on the active lever per 1 h. During the extinction phase, the rats were injected at least 3 times with saline (intraperitoneally) 15 min before the sessions to habituate them to the injection procedure. The extinction session during which the rats reached the extinction criterion after the intraperitoneal saline injection served as a baseline against which the effect of cocaine priming injections on reinstatement was compared. One P rat did not reach the extinction criterion after 31 extinction sessions and was excluded. The effect of priming injections of cocaine (5.0 and 10.0 mg/kg, i.p.; 15 min pretreatment time) on reinstatement of cocaine seeking was examined in the P and NP rats in a counterbalanced manner. Two to four extinction sessions were conducted between the tests of each priming dose until the extinction criterion was again achieved. Finally, at the end of the experiment, the rats were injected in a counterbalanced order with either saline or nicotine (0.15 mg/kg, s.c.) during two daily sessions, and the effect of these injections on reinstatement of cocaine seeking was determined.

Statistical analyses. The data from the different phases of the experiments were analyzed with ANOVAs using the appropriate between- and within-subjects factors (see Results). Significant effects ($p < 0.05$) were followed by *post hoc* (Newman–Keuls) tests. Because the number of responses on the inactive lever was fewer than three per hour in the different phases of the experiments presented below, these data are not shown.

Results

Experiment 1: Sucrose

Experiment 1a

The rats in both groups rapidly learned the operant task within one to two sessions. During the first three sessions, sucrose intake was lower in the P rats than in the NP rats (P rats: 10.5 ± 1.3 ml per 2 h/d; NP rats: 13.4 ± 0.8 ml per 2 h/d; $n = 15$ per line; $F_{(2,56)} = 4.9$; $p < 0.05$; for effect of rat line by training day). Over the last six sessions, however, the P rats increased their sucrose intake, whereas the sucrose intake in the NP rats remained stable, resulting in higher intake in the P rats (P rats: 19.9 ± 1.0 ml per 1 h/d; NP rats: 12.9 ± 0.7 ml per 1 h/d; $F_{(1,28)} = 34.5$ and $F_{(5,140)} = 2.9$; $p < 0.05$; for effects of rat line and rat line by training day).

Experiment 1b

As in Experiment 1a, the lever responding for sucrose of the P rats was initially lower than that of the NP rats. Over time, however, the P rats increased their lever responding to a greater degree than the NP rats, resulting in higher intake in the P rats during sessions 6–10 (Fig. 1a). The statistical analysis for the number of sucrose rewards earned revealed significant effects of rat line ($F_{(1,19)} = 8.7$; $p < 0.01$) and rat line by training day ($F_{(9,171)} = 10.9$; $p < 0.01$). The P rats also self-administered more sucrose during the subsequent concentration–response determination (Fig. 1b). The statistical analysis of the number of sucrose rewards earned revealed significant main effect of rat line ($F_{(1,19)} = 42.2$; $p < 0.01$) and significant interaction effect of rat line by sucrose concentration ($F_{(3,57)} = 5.28$; $p < 0.01$).

Experiment 2: Nicotine

Self-administration

Figure 2, a and b, presents the mean $\pm$ SEM number of infusions and active lever responses during the first 24 sessions of training under FR-1, FR-2, and FR-5 reinforcement schedules (nicotine dose of 0.03 mg/kg per infusion). Nicotine intake during this time period was substantially higher in the P rats than in the NP rats

Figure 1. Sucrose self-administration in P and NP rats. **a**, Mean $\pm$ SEM number of sucrose deliveries during the first 10 d of sucrose (10%) self-administration (0.19 ml per reward delivery) under an FR-1 reinforcement schedule (each lever press was reinforced). **b**, Mean $\pm$ SEM number of sucrose deliveries as a function of the sucrose concentration; data are from the concentration–response determination during days 11–22 of sucrose self-administration (3 d per dose). *Different from the NP group; $p < 0.05$ (Newman–Keuls *post hoc* test); $n = 11$ per line.

(Fig. 2a). Both the P and the NP rats, however, maintained their daily nicotine intake when the schedule requirement was increased to FR-2 and FR-5 by increasing their active lever responding (Fig. 2b). For the number of infusions under the FR-1 schedule, significant effects were found for rat line and rat line by training day ($F_{(1,19)} = 19.9$ and $F_{(9,171)} = 6.8$; $p < 0.01$). Under the FR-2 schedule, significant effects were found for rat line and rat line by training day ($F_{(1,19)} = 35.9$ and $F_{(4,76)} = 4.3$; $p < 0.01$), whereas for the FR-5 schedule, there was a significant effect of rat line ($F_{(1,19)} = 48.1$; $p < 0.01$).

Figure 2, c and d, presents the mean $\pm$ SEM number of infusions and daily intake (milligrams per kilogram) during the dose–response determination (sessions 25–33). Independent of the nicotine dose, the P rats self-administered more nicotine than the NP rats. Overall, for both the P and NP rats, increasing the dose of nicotine led to large increases in their daily intake. For the P rats, increasing the nicotine dose led to decreases in the number of infusions, whereas for the NP rats, the dose–response curve remained relatively flat. The statistical analysis for the number of infusions revealed significant effects of rat line and rat line by nicotine dose ($F_{(1,62)} = 99.8$ and $F_{(1,62)} = 7.2$; $p < 0.01$). The statistical analysis for nicotine intake (milligrams per kilogram)

Figure 2. Nicotine self-administration in P and NP rats. **a, b**, Mean $\pm$ SEM number of nicotine infusions and active lever responses during the first 24 d of nicotine self-administration (0.03 mg/kg per infusion) under FR-1, FR-2, and FR-5 reinforcement schedules. **c, d**, Mean $\pm$ SEM number of nicotine infusions and nicotine intake (milligrams per kilogram); data are from the dose–response determination during days 25–33 of nicotine self-administration training (3 d per dose). *Different from the NP group; $p < 0.05$ (Newman–Keuls *post hoc* test); $n = 9–12$ per line.

Figure 3. Extinction and reinstatement of nicotine seeking in P and NP rats. **a**, Mean $\pm$ SEM number of responses on the previously active lever during the first seven sessions of the extinction phase. During this phase, lever responding led to saline infusions and the illumination of the cue light previously paired with nicotine infusions. **b**, Mean $\pm$ SEM number of responses on the previously active lever during the tests for reinstatement of nicotine seeking induced by priming injections of saline or nicotine (0.15 mg/kg, s.c.). During the reinstatement tests, lever responding was not reinforced with nicotine. *Different from the NP group; $p < 0.05$; $n = 9–12$ per line.

revealed significant main effects of nicotine dose ($F_{(2,62)} = 4.3$; $p < 0.05$) and rat line ($F_{(1,62)} = 30.6$; $p < 0.01$).

Extinction

Figure 3a presents the mean $\pm$ SEM number of active lever responses during the first seven extinction sessions, during which all rats were exposed to the extinction conditions. Lever responding in the presence of the nicotine-associated cues in the extinction sessions was substantially higher in the P rats than in the NP rats. The statistical analysis of the first seven extinction sessions revealed significant effects of rat line and rat line by extinction day ($F_{(1,19)} = 34.8$ and $F_{(6,114)} = 5.9$; $p < 0.01$). The P rats were also more resistant to extinction, as indicated by the higher number of extinction sessions that they needed to reach the extinction criterion of 15 presses on the active lever per hour (P rats: 8.9 ± 2.0 ; NP rats: 2.00 ± 0.8 ; $F_{(1,19)} = 28.3$; $p < 0.01$ for the effect of rat line).

Reinstatement

Figure 3b presents the mean $\pm$ SEM number of active lever responses during the tests for reinstatement after noncontingent priming injections of saline or nicotine; these tests were conducted after 7–23 extinction sessions when rats met the extinction criterion of fewer than 15 responses on the active lever. Nicotine priming injections reinstated lever responding in the P rats but not in the NP rats. The statistical analysis revealed significant effects of rat line and rat line by nicotine dose ($F_{(1,39)} = 14.8$ and $F_{(1,39)} = 9.7$; $p < 0.01$).

Experiment 3: Cocaine

Self-administration

Figure 4, **a** and **b**, shows the mean $\pm$ SEM number of cocaine infusions and active lever presses during the first 16 sessions of training under the FR-1, FR-2, and FR-5 reinforcement schedules (cocaine dose of 0.75 mg/kg per infusion). There were no significant P–NP differences for cocaine self-administration under these reinforcement schedules. During the initial seven sessions under the FR-1 schedule, both the P and NP rats increased their cocaine intake over time ($F_{(6,114)} = 6.9$; $p < 0.01$ for the effect of

Figure 4. Cocaine self-administration in P and NP rats. *a, b*, Mean $\pm$ SEM number of cocaine infusions and active lever responses during the first 14 d of cocaine self-administration (0.75 mg/kg per infusion) under FR-1, FR-2, and FR-5 reinforcement schedules. *c, d*, Mean $\pm$ SEM number of cocaine infusions and cocaine intake (milligrams per kilogram); data are from the dose–response determination during days 15–22 of cocaine self-administration (2 d per dose; $n = 9–11$ per line).

training day). The P and NP rats maintained their daily cocaine intake when the schedule requirement was increased from FR-1 to FR-2 and then to FR-5 by increasing their lever responding (Fig. 4*a,b*). There were no P–NP differences for the number of cocaine infusions or active lever presses under the FR-1, FR-2, and FR-5 reinforcement schedules ($p > 0.1$). Figure 4, *c* and *d*, presents the mean $\pm$ SEM number of cocaine infusions and daily intake (milligrams per kilogram) during the subsequent dose–response determination (two sessions per dose); there were no P–NP differences. Both the P and NP rats demonstrated the characteristic responding on the descending limb of the cocaine dose–response curve (Yokel, 1987): decreases in the number of infusions per session for increasing cocaine doses (Fig. 4*c*) and overall increases in total cocaine intake (Fig. 4*d*). The statistical analysis

for the number of cocaine infusions and total intake revealed a significant effect of cocaine dose ($F_{(3,55)} = 194.0$ and $F_{(3,55)} = 50.1$; $p < 0.01$, respectively). The effects of rat line and rat line by cocaine dose were not significant ($p > 0.1$).

Extinction

Figure 5*a* presents the mean $\pm$ SEM number of active lever responses during the first 14 extinction sessions, during which all rats were exposed to the extinction conditions. Lever responding in the presence of the cocaine-associated cues during the extinction sessions was higher in the P rats than in the NP rats. The statistical analysis of the first 14 extinction sessions revealed significant effects of rat line by day ($F_{(13,234)} = 1.76$; $p = 0.05$) and extinction day ($F_{(13,234)} = 18.0$; $p < 0.01$). During the first 14 d of extinction, active lever responding was consistently higher in the P rats, which lever pressed $\sim 70\%$ more than the NP rats on the first extinction day ($F_{(1,18)} = 5.1$; $p < 0.05$). Additional evidence supporting the increased resistance to extinction in the P rats is the significantly higher number of extinction sessions that it took for the P rats to reach the extinction criterion of 15 presses on the active lever per hour (P rats: 12.4 ± 1.6 ; NP rats: 6.7 ± 1.4 ; $F_{(1,18)} = 7.1$; $p < 0.05$ for rat line).

Reinstatement

Figure 5*b* presents the mean $\pm$ SEM number of active lever responses during the tests for reinstatement after noncontingent priming injections of saline or cocaine; these tests were conducted after 14–31 extinction sessions when rats met the extinction criterion of fewer than 15 responses on the active lever. Injections of the low dose of cocaine priming (5 mg/kg) reinstated lever responding in the P rats to a greater degree than in the NP rats; no P–NP differences were observed with the higher cocaine dose (10 mg/kg). The statistical analysis revealed effects of cocaine dose ($F_{(2,18)} = 26.9$; $p < 0.01$), rat line ($F_{(1,18)} = 4.3$; $p < 0.05$), and rat line by cocaine dose interaction that approached significance ($F_{(2,18)} = 2.8$; $p = 0.07$). In addition, in subsequent tests, nicotine priming injections reinstated cocaine seeking in the P rats but not the NP rats (Fig. 5*c*). The statistical analysis revealed significant effects of nicotine dose ($F_{(1,16)} = 19.8$; $p < 0.01$), rat line ($F_{(1,16)} = 70.2$; $p < 0.01$), and rat line by nicotine dose ($F_{(1,16)} = 32.3$; $p < 0.01$).

Discussion

We assessed three measures of nicotine-taking behavior in alcohol-naïve offspring of P and NP rats that were selectively bred for high and low alcohol intake (Li et al., 1993). First, we used a drug self-administration procedure that has been used to assess the reinforcing effects of nicotine and other drugs (Picciotto and Corrigan, 2002; Wise, 2004). Second, we used an extinction procedure that has been used to assess the conditional motivational effects of cues previously paired with nicotine and other drug and nondrug reinforcers (Balleine and Dickinson, 1998; Everitt et al., 1999; Caggiula et al., 2001; Shalev et al., 2002; Lu et al., 2004a). Third, we used a reinstatement procedure that has been used to assess relapse to alcohol and drug seeking induced by acute reexposure to the self-administered drug or other stimuli (Stewart, 2000; Le and Shaham, 2002; Shaham et al., 2003; Weiss, 2005). We found that nicotine-taking behavior in these tests was significantly higher in P rats than in NP rats. These data, which were obtained from preclinical self-administration and relapse models, support the hypothesis that nicotine and alcohol addiction share a common genetic vulnerability.

Figure 5. Extinction and reinstatement of cocaine seeking in P and NP rats. *a*, Mean $\pm$ SEM number of responses on the previously active lever during the first 14 sessions of the extinction phase. During this phase, lever responding led to saline infusions and the illumination of the cue light previously paired with cocaine infusions. *b*, Mean $\pm$ SEM number of responses on the previously active lever during the tests for reinstatement of cocaine seeking induced by priming injections of saline and cocaine (5 and 10 mg/kg, i.p.). *c*, Mean $\pm$ SEM number of responses on the previously active lever during the tests for reinstatement of cocaine seeking induced by priming injections of saline and nicotine (0.15 mg/kg, s.c.). During the reinstatement tests, lever responding was not reinforced with cocaine. *Different from the NP group; $p < 0.05$; $n = 9–11$ per line.

Nicotine-taking behavior in P and NP rats

Over a range of nicotine doses and response costs, P rats self-administered more nicotine than NP rats. This effect is not the result of learning deficits. NP rats rapidly learned to self-administer oral sucrose and, over the first 3 d of training, acquired the operant task more rapidly than P rats (Fig. 1). The P–NP differences are also not the result of the failure of NP rats to acquire nicotine self-administration. NP rats increased their lever responding and consequently maintained a relatively stable daily nicotine intake when the schedule requirement was changed from FR-1 to FR-2 and FR-5 (Fig. 2*a*). Furthermore, the pattern of nicotine self-administration and the daily intake in NP rats (~ 12 infusions per hour for a dose of 0.03 mg/kg under an FR-5 schedule) was similar to those reported for Long–Evans and Wistar rats (Corrigall and Coen, 1989; Chiamulera et al., 1996; Shaham et al., 1997).

We interpret the upward shift in the nicotine dose–response curve (Fig. 2*c,d*) in P rats to suggest that nicotine has greater reinforcing effects in P rats than in NP rats. This interpretation is based on the conceptualization of Piazza and colleagues (2000) who argued, on the basis of several lines of evidence, that upward shifts in the dose–response curve in drug self-administration studies reflect increases in the reinforcing effects of the drug. An alternative interpretation is that the higher number of infusions on the descending limb of the nicotine dose–response curve (a shift to the right of the curve) in P rats (Fig. 2*c*) is caused by decreases in the reinforcing effects of nicotine in these rats. This interpretation, however, is unlikely. The findings of higher lever responding in P rats during the extinction and reinstatement tests (Fig. 3*a,b*) are not compatible with the notion that nicotine is a weaker reinforcer in P rats than in NP rats. Furthermore, under our training conditions, manipulations that decrease the reinforcing effects of nicotine, such as injections of nicotine receptor antagonists or lesions of the mesolimbic dopamine system, decrease rather than increase nicotine self-administration (Rose and Corrigall, 1997; Picciotto and Corrigall, 2002).

Nicotine injections enhance the conditioned reinforcing effects of stimuli paired with natural reinforcers (Olausson et al., 2004), and recent studies have demonstrated a critical role of environmental cues in nicotine self-administration (Caggiula et

al., 2001; Donny et al., 2003). These investigators found that lever presses that lead to the delivery of a brief visual stimulus, a weak reinforcer in rats (Deroche-Gamonet et al., 2002; Donny et al., 2003), are increased to similar degrees by contingent or noncontingent nicotine infusions. On the basis of these findings, Caggiula and colleagues (2001) suggested that nicotine-taking behavior is primarily the result of the ability of nicotine to potentiate the reinforcing effects of other stimuli in the drug environment. In our study, as in many other nicotine self-administration studies, lever presses were accompanied by a light cue. Thus, on the basis of the hypothesis of Caggiula et al. (2001), increases in nicotine-taking behavior in P rats may be caused by increased sensitivity to the effects of nicotine on behaviors maintained by nondrug stimuli in the drug environment, rather than differences in the reinforcing effects of acute un-

conditioned nicotine. To the degree that drug priming injections reinstate drug seeking by restoring the incentive value of extinguished drug cues (Stewart et al., 1984), the finding that noncontingent nicotine priming injections reinstate lever responding in P rats but not NP rats (Fig. 3*b*) is compatible with this speculation.

Finally, P–NP differences in extinction responding in the presence of nicotine (or cocaine) cues may reflect genetic differences in sensitivity to drug-associated cues; however, for the nicotine-trained rats, drug intake during the self-administration phase was higher in P rats than in NP rats. Thus, P–NP differences in extinction responding may be caused by additional nicotine–cue pairing in P rats, which subsequently resulted in increased responsiveness to nicotine cues in these rats. The data from Experiment 3, however, tentatively support the notion that genetics may play a role in P–NP differences in responsiveness to drug cues. We found P–NP differences in the response to cocaine cues in the extinction tests, despite the fact that the number of cocaine–cue pairings during self-administration was similar in the two rat lines.

Sucrose- and cocaine-taking behavior in P and NP rats

We determined the generality of our findings with nicotine by assessing P–NP differences in sucrose self-administration, cocaine self-administration, cocaine seeking induced by cocaine cues in extinction tests, and cocaine (and nicotine) priming-induced reinstatement tests. Over a range of sucrose concentrations, P rats self-administered more sucrose than NP rats. This finding is consistent with previous studies in which it was found that the P rats consume greater amounts of sucrose (Stewart et al., 1994; Eiler et al., 2005). Our data for sucrose self-administration are also consistent with results from human studies on the association between alcoholism and sucrose palatability and preference (Kampov-Polevoy et al., 1997, 1999, 2003).

A major finding here is that over a range of doses, cocaine self-administration was remarkably similar in P and NP rats. In contrast, P–NP differences in cocaine seeking emerged in subsequent extinction and cocaine priming-induced reinstatement tests; in both cases, lever responding was somewhat higher in P rats than in NP rats. Marked P–NP differences also were found

during a final test for nicotine priming-induced reinstatement of cocaine seeking (Fig. 5c). The lack of P–NP differences in cocaine self-administration under fixed ratio schedules, a procedure commonly used to measure the acute reinforcing effects of cocaine (Wise, 1978; Roberts et al., 1980), appears to be inconsistent with results from correlational human data on comorbidity of cocaine and alcohol dependence (Bierut et al., 1998; Merikangas et al., 1998; Nurnberger et al., 2004). Unlike alcohol and nicotine, however, for which it was established that genetic factors contribute significantly to comorbidity between these drugs (True et al., 1999), genetic contributions to alcohol and cocaine comorbidity have not yet been clearly established (Goldman and Bergen, 1998; Goldman et al., 2005). In interpreting the potential discrepancy between human cocaine–alcohol comorbidity and the present data on the lack of P–NP differences in cocaine self-administration, it is also important to note that differences in the magnitude of the acute reinforcing effects of the drug, as measured in self-administration models, do not readily predict compulsive drug use and relapse in humans (Volkow and Fowler, 2000; Kalivas and Volkow, 2005) and laboratory rats (Shalev et al., 2002; Deroche-Gamonet et al., 2004; Vanderschuren and Everitt, 2004). In this regard, to the degree that extinction and reinstatement procedures model human drug relapse, the findings of P–NP differences in extinction responding and cocaine- and nicotine-induced reinstatement of cocaine seeking (Figs. 3, 5) are consistent with the notion of a general genetic factor in human addictions (Uhl et al., 2002), because relapse vulnerability is a core feature of addiction (O'Brien, 2005).

Finally, the findings on the lack of P–NP differences in cocaine self-administration are consistent with those of Eiler et al. (2005), who reported lack of P–NP differences for medial forebrain bundle stimulation threshold, an established measure of reward sensitivity (Wise, 1996). The findings of the lack of P–NP differences in cocaine self-administration and brain stimulation reward indicate that P–NP differences in nicotine-taking behavior are not the result of general reward deficits in NP rats.

Concluding remarks

The prevalence of smoking in human alcoholics is much higher than in the general population, and results from twin studies have led to the hypothesis that a shared genetic vulnerability underlies alcohol and nicotine addiction. Here, we provided experimental evidence from rat models of drug self-administration and relapse that supports this hypothesis. Alcohol-naïve offspring of rats that were selectively bred for high and low alcohol intake demonstrated differences in nicotine-taking behavior that were as profound as those found previously with P and NP rats for alcohol-taking behavior. These findings suggest that these lines of rats can be as useful for the study of determinants of nicotine addiction as they have been for the study of alcohol addiction in animal models.
