The proto-oncogene ras plays a critical role in cell proliferation and differentiation. However, ras genes are abundantly expressed in the adult CNS, although neuronal cells normally do not proliferate. Recently, several lines of evidence implicated the involvement of Ras signaling pathway in synaptic plasticity. To explore the role of the Ras proteins in the CNS, we generated knock-out mice lacking the H-ras gene and then used them to study the roles of Ras in synaptic transmission and plasticity. An investigation of protein phosphorylation and synaptic transmission in H-ras null mutant mice has shown that the NMDA receptor is a final target molecule of the Ras protein pathway in the CNS. In the H-ras null mutant hippocampus, the tyrosine phosphorylation of NR2A (ε1) and NR2B (ε2) subunits of NMDA receptors is increased, and, correspondingly, NMDA synaptic responses are selectively enhanced. In addition, long-term potentiation is markedly enhanced in mutant mice, most likely because of a selective enhancement of NMDA synaptic responses. Therefore, although Ras proteins have been implicated in cell proliferation and differentiation, the regulation of activity-dependent synaptic plasticity in the adult animals by downregulation of the phosphorylation of the NMDA receptor may be another major and pivotal role for H-Ras protein.

Key words: long-term potentiation; NMDA receptor; H-Ras; tyrosine phosphorylation; hippocampus; mutant mice

magnitudes of mutant LTP is almost double that of wild-type mice. This effect is most likely attributable to a selective enhancement of the NMDA synaptic responses induced by an increase in the tyrosine phosphorylation of NMDA receptors. Therefore, the protein encoded by the H-ras gene is a key molecule that regulates LTP induction by the downregulation of the NMDA receptor activity.

MATERIALS AND METHODS

Mice. When comparing wild-type and H-ras(−/−) mice, littermates from heterozygous parents were used in most cases, although in some cases, age-matched animals were also used. All experiments using mice were performed in accordance with the animal use guidelines at each institute.

_in situ_ hybridization. The nucleotide sequence of the probe was complementary to the H-ras cDNA (5′GCAGGACCACCTCCTACGGG- GTGGGTCATGGTCGCAATTTAATG3′). Brains of adult wild-type and mutant mice were quickly removed after ether anesthesia and frozen in powdered dry ice. The sagittal sections were cut on a cryostat at a thickness of 25 μm and mounted onto silane-coated glass slides. The sections were immersed in 4% paraformaldehyde for 10 min and acetylated in 0.25% acetic anhydride–0.1 M triethanolamine, pH 8.0, for 10 min at room temperature. After prehybridization, the sections were incubated overnight at 4°C in the solution containing 50% deionized formamide, 4× SSC (1× SSC: 0.15 M NaCl and 0.015 M sodium citrate, pH 7.4), 1× Denhardt’s solution (0.02% each of polyvinylpyrrolidone, bovine serum albumin, and Ficoll), 1% sodium N-lauryl sarcosinate ( Sarkosyl), 0.1 M phosphate buffer, pH 7.2, 250 μg/ml heat-denatured salmon sperm DNA, 10% dextran sulfate, 100 mM dithiothreitol, and 35S-labeled oligonucleotide probe (5–10 × 105 cpm/μl). The sections were then washed in 0.1× SSC–0.1% Sarkosyl at 50°C four times for 30 min. The sections were exposed to Hyperfilm β-max (Amersham Pharmacia Biotech, Uppsala, Sweden) for 2 weeks at room temperature.

_Western blot_. The hippocampus was homogenized in radiolmmunoprecipitation assay (RIPA) buffer (20 mM Tris-HCL, 150 mM NaCl, 0.1% SDS, 1% sodium deoxycholate, 1% Triton X-100, 2 mM EDTA, 10 mM NaF, 1 mM sodium orthovanadate, 20 μg/ml aprotinin, and 20 μg/ml leupeptin). Cellular fractions containing synaptosomes and PSDs were prepared as described by Carlin et al. (1980). Proteins were separated by electrophoresis on SDS-PAGE. The proteins were then transferred to the polyvinylidene difluoride (PVDF) membranes (Bio-Rad, Hercules, CA), and immunoblots were probed with monoclonal anti-NR2A antibodies (Santa Cruz Biotechnology). The hippocampus was homogenized in radioimmunoprecipitation assay (RIPA) buffer containing 0.5% SDS. After boiling the lysates, they were diluted by RIPA buffer lacking SDS to 0.1% SDS (Sheng et al., 1994) and centrifuged for 20 min at 18,000 × g. The supernatants were incubated at 4°C with protein G-Sepharose (Amersham Pharmacia Biotech) overnight. After centrifugation, 200 μg of precleared lysates were incubated with a monoclonal anti-NR2A antibody (a gift from Dr. S. Nakashima, Kyoto University Faculty of Medicine, Kyoto, Japan) or affinity-purified polyclonal anti-NR2B antibodies (a gift from Drs. T. Yamamoto and H. Umemori, Institute of Medical Science, University of Tokyo, Tokyo, Japan) raised to synthetic peptide HGAVPGRFQKDI corresponding to amino acids 1407–1418 of NR2B at 4°C for 1 hr. Immune complexes were isolated by the addition of protein G-Sepharose followed by incubation for 1 hr at 4°C. The resulting immune complexes were washed five times with RIPA buffer, resuspended in Laemli sample buffer, and boiled for 5 min. Proteins were separated by SDS-PAGE. The proteins were then transferred to PVDF membranes, and immunoblots were probed with an anti-phosphotyrosine antibody (anti-PY) linked to horse radish peroxidase (RC20:HRPO; Transduction Laboratories, Lexington, KY). The amount of anti-PY bound to the 180 kDa band was quantified by densitometry of the x-ray films. The ratio of the amount of anti-PY bound in wild-type and mutant mice to the mean of that in wild-type mice on the same blot was calculated, and then the normalized value on different blots were averaged.

To examine the subunit composition and tyrosine phosphorylation of the heteromeric complexes of native NMDA receptors, hippocampal lysates solubilized in RIPA buffer were immunoprecipitated with polyclonal anti-NR1 antibodies (Upstate Biotechnology, Lake Placid, NY), and immunoblots were probed with polyclonal anti-NR1 (Chemicon, Temecula, CA), polyclonal anti-NR2A (Santa Cruz Biotechnology), polyclonal anti-NR2B (Santa Cruz Biotechnology), anti-PY, and polyclonal anti-PSD-95 (Santa Cruz Biotechnology) antibodies. The PTK activity was assayed using Universal Tyrosine Kinase Assay Kit (Takara Shuzo, Otsu, Shiga, Japan). The procedure was a modification of that described by Rijken et al. (1991). Protein lysates were incubated with a substrate poly(Glu-Tyr) immobilized to microplates and unlabeled ATP in the presence of 1 mM sodium-orthovanadate and 50 mM NaF. After termination of the reaction, the tyrosine phosphorylation was measured by ELISA with anti-phosphotyrosine (PY20:HRPO) and HRPO substrate, 3,5,5′-tetramethylbenzidine. One unit (U) is defined as the activity of c-Src protein, which can transfer 1 pmol of γ-phosphate of ATP to the substrate per minute.

The data are expressed as the means ± SEMs. Student’s _t_ test was used to determine whether there was a significant difference (_p_ < 0.05) in the mean between the two sets of data.

Electrophysiology. Hippocampal slices (400-μm-thick) were prepared from 6- to 12-week-old mice and placed in a holding chamber for at least 1 hr. A single slice was then transferred to the recording chamber. The chamber, submerged beneath a continuously perfusing medium that had been saturated with 95% O2 and 5% CO2. The composition of the medium was (in mM): 119 NaCl, 2.5 KCl, 1.3 MgSO4, 2.5 CaCl2, 1.0 NaH2PO4, 26.2 NaHCO3, and 11 glucose. All the perfusing solutions contained 100 μM piroxicam to block GABAA receptor-mediated inhibitory synaptic responses. The field potential recordings were made with a glass electrode (3 M NaCl) placed in the stratum radiatum. The whole-cell pipette solution contained (in mM): 122.5 cesium gluconate, 17.5 CsCl, 10 HEPES, 0.2 EGTA, 8 NaCl, 2 Mg-ATP, and 0.3 Na3-GTP, pH 7.2 (osmolarity 290–300 mOsm). In the whole-cell recordings, the values of the membrane potential were corrected for the liquid junction potential at the electrode tip. An Axopatch 1D amplifier (Axon Instruments, Foster City, CA) was used, and the signal was filtered at 1 kHz, digitized at 5–10 kHz, and stored on an IBM-compatible computer equipped with a Labmaster analog-to-digital board (Axon Instruments). For evoking synaptic responses, a bipolar tungsten stimulating electrode was placed in the stratum radiatum, and Schaffer collateral–commissural fibers were stimulated at 0.1 Hz. For LTP experiments, the stimulus strength was adjusted so that it gave rise to AMPA receptor-mediated EPSPs of the slope value between 0.10 and 0.15 mV/msec. For the analysis of EPSPs, we measured their early rising phase to avoid contamination of voltage-dependent components as much as possible. All experiments were done at room temperature. The data are expressed as the means ± SEMs. Student’s _t_ test was used to determine whether there was a significant difference (_p_ < 0.05) in the mean between the two sets of data. The majority of electrophysiological experiments were performed in a blind manner, and the results were essentially identical to those of the nonblind experiments, and thus all the data were pooled.

RESULTS

Expression of H-ras gene

The distribution of H-ras mRNAs in the brain examined by _in situ_ hybridization showed that the H-ras gene is abundantly expressed in the CNS, including the hippocampus, cerebral cortex, cerebellum, and striatum, of normal mice (Fig. 1a). A Western blot analysis of the amount of the H-ras protein in whole-cell extracts from the cerebral cortex or in the fraction containing synaptosomes and mitochondria, the synaptosome fraction, and the PSD fraction (Carlin et al., 1980) showed that H-ras protein exists in the synaptosome but not in the PSD fraction (Fig. 1d). Because we confirmed the existence of H-ras protein in neurons, mice lacking the H-ras gene [H-ras(−/−)] were generated to examine the roles of Ras proteins in the CNS. H-ras(−/−) mice appeared to be healthy and bred and developed normally. Their life spans were the same as those of the wild-type littermates, and their behavior also appeared to be normal. A histological examination of various brain regions, including the striatum, hippocampus (Fig. 1d), cerebral cortex, and cerebellum in the mutant mice showed no obvious morphological abnormalities at the micro-
scopic level. In situ hybridization analyses of brain slices with oligonucleotide probes indicated that H-ras mRNAs are absent in H-ras(−/−) mice (Fig. 1b). We examined the amount of Ras proteins in the H-ras(−/−) hippocampus lysate. Immunoreactivity with an anti-Ras antibody that recognizes all three types of Ras protein was drastically decreased in the mutant lysate (Fig. 1f) compared with that in the wild-type lysate, suggesting that most of Ras proteins are the H-Ras proteins in H-ras(−/−) mice (Fig. 1f).

Increase in tyrosine phosphorylation of NMDA receptors without an alteration of the subunit composition in H-ras(−/−) mice

We next examined the tyrosine phosphorylation and the subunit composition of NMDA receptors in H-ras(−/−) mice. We first examined the tyrosine phosphorylation of NR2A and NR2B after a dissociation of the NMDA receptor complexes (Sheng et al., 1994). The proteins (200 µg) from the wild-type and H-ras(−/−) lysates were boiled in 0.5% SDS followed by dilution into RIPA buffer and then were immunoprecipitated with anti-NR2A or anti-NR2B antibodies. The resulting immune complexes were blotted with anti-PY (Fig. 2a). The amounts of anti-PY bound to both NR2A (155 ± 14% of wild type; n = 16) and NR2B (172 ± 23% of wild type; n = 16) in the H-ras(−/−) were significantly larger (p < 0.01) than those in the wild type (NR2A, 100 ± 11%; n = 16; NR2B, 100 ± 5%; n = 16). Next, the hippocampus proteins solubilized in RIPA buffer were coimmunoprecipitated by an anti-NR1 antibody to examine the subunit composition and tyrosine phosphorylation of the heteromeric complexes of native NMDA receptors in wild-type and mutant mice. The amount of NR1, NR2A, and NR2B coprecipitated with the anti-NR1 antibody was not altered in the H-ras(−/−) lysates (Fig. 2b). The same blot probed with anti-PY showed a single 180 kDa band (Fig. 2b, bottom right). Because no 180 kDa tyrosine-phosphorylated protein other than NR2A or NR2B is known in the NMDA receptor complex, the tyrosine phosphorylation of the 180 kDa protein coprecipitated with the anti-NR1 antibody is likely to correspond to that of NR2A and NR2B. Anti-PY bound to the 180 kDa protein was significantly larger (p < 0.05) in the H-ras(−/−) lysates (137 ± 3% of wild type; n = 3) than that in the wild type (100 ± 18%; n = 3) (Fig. 2b), suggesting that the phosphorylation of NR2A and NR2B was increased in the NMDA receptor complex in the H-ras(−/−) mice. Furthermore, we examined the amount of PSD-95 proteins that may be required for the localization of NMDA receptors to synapses and found that the amount of PSD-95 proteins in the NMDA receptor complex is not significantly changed in H-ras(−/−) mice (Fig. 2c).

Because we found the increase of tyrosine phosphorylation of NR2A and NR2B in the H-ras(−/−) hippocampus, we measured PTK activity with the synthetic peptide poly(Glu-Tyr) as a general PTK substrate in the hippocampal lysates in the presence of tyrosine phosphatase inhibitors (Rijksen et al., 1991). The H-ras(−/−) lysates had a significant 18% increase in the activity of PTKs when compared with wild-type lysates (wild type, 3.03 ± 0.09 × 10−2 U/µg; n = 8; H-ras(−/−), 3.56 ± 0.13 × 10−2 U/µg, n = 8; p < 0.01). These results suggest that H-Ras proteins regulate NMDA receptors by downregulation of tyrosine phosphorylation without changing the subunit composition and interaction between NMDA receptors and PSD-95 proteins in normal animals.

Upregulation of NMDA receptor-mediated synaptic responses in H-ras-deficient mice

We next investigated excitatory synaptic transmission in hippocampal slices of H-ras(−/−) and wild-type mice to study the effects of these biochemical changes on the synaptic functions in the CNS. EPSCs were evoked in CA1 pyramidal cells using whole-cell patch-clamp techniques by stimulating Schaffer collateral–corticothalamic fibers in the stratum radiatum. We first examined whether NMDA receptor-mediated EPSCs are modified by the increase in phosphorylation of NMDA receptor subunits in H-ras(−/−) mice (Fig. 3a,b). AMPA receptor-mediated EPSCs were recorded at a membrane potential of −90 mV in a voltage-clamp mode. NMDA EPSCs were then measured at the same stimulus strength in the presence of 6-cyano-7-nitroquinoxaline-2,3-dione (CNQX) (10 µM), a non-NMDA receptor antagonist, at +40 mV to reduce the voltage-dependent Mg2+ block of the NMDA receptor channel (Mayer et al., 1984; Nowak et al., 1984). The ratio of NMDA to AMPA EPSC amplitudes (Sakimura et al., 1995) was significantly larger (p < 0.02) (Fig. 3b) in H-ras(−/−) mice (59.9 ± 5.2%, n = 12 cells and 6 mice) than in wild-type mice (44.3 ± 4.9%, n = 13 cells and 7 mice), suggesting that the modulation of NMDA receptors may enhance the NMDA synaptic responses in H-ras(−/−) mice. However, it is also possible that the larger NMDA/AMPA ratio is attributable to a selective reduction of AMPA synaptic responses. To differentiate these possibilities, we examined the input–output relationships of the AMPA and NMDA EPSPs in wild-type and H-ras(−/−) mice.
Tyrosine phosphorylation of NR2A and NR2B in the wild-type (+/+) and H-ras(−/−) hippocampus. a. Hippocampal proteins (200 μg) solubilized in boiling SDS followed by dilution into RIPA buffer were incubated with anti-NR2A or anti-NR2B antibodies. Immunoprecipitation (IP) with anti-NR2A or anti-NR2B antibodies was separated by SDS-PAGE and immunoblotted with the anti-PY. The amount of antibodies bound to each band was quantified by densitometry of the x-ray films, and values were normalized to the mean of wild-type values. The normalized amount of anti-PY bound to NR2A and NR2B in H-ras(−/−) mice was significantly larger (p < 0.01) than that in wild-type mice. The insets are representative immunoblots with the anti-PY. b, Hippocampus proteins (200 μg) solubilized in RIPA buffer were incubated with an anti-NR1 antibody. Immunoprecipitation with the anti-NR1 antibody was separated by SDS-PAGE and transferred to PVDF membrane. The membrane was then analyzed by sequential blotting using anti-NR1, anti-NR2A, anti-NR2B, and anti-PY antibodies. The amount of NR1, NR2A, and NR2B coprecipitated with the anti-NR1 antibody was not altered in the H-ras(−/−) lysates. Tyrosine phosphorylation of 180 kDa proteins coprecipitated with the anti-NR1 antibody was significantly larger (p < 0.05) in the H-ras(−/−) lysates than that in the wild type. c. The input–output relationships of AMPA EPSCs (open circles) in wild-type (filled circles; n = 9 cells, 5 mice) and H-ras(−/−) (filled circles; n = 7 cells, 4 mice) mice. Current amplitudes, which were larger in H-ras(−/−) mice, were normalized to the value obtained at +40 mV for easier comparison. d, The input–output relationships of AMPA EPSCs of wild-type (open circles; n = 10 slices, 5 mice) and H-ras(−/−) (filled circles; n = 10 slices, 5 mice) mice. Sample traces in the inset represent the responses evoked with five different stimulus intensities varying from 1.35 to 1.71 V. e, The input–output relationships of NMDA EPSCs of wild-type (open circles; n = 14 slices, 7 mice) and H-ras(−/−) (filled circles; n = 14 slices, 7 mice) mice. CNQX (10 μM) was present to block AMPA receptor-mediated synaptic responses. Sample traces in the inset represent the responses evoked with five different stimulus intensities varying from 2.16 to 2.88 V. Stimulation with higher intensities was used to overcome the Mg2+ block of the NMDA receptor. As shown in the inset, in H-ras(−/−) mice, NMDA EPSCs were often accompanied by bursting activity, presumably because of their large size. In some experiments, 40 μM t-APV was applied at the end of the experiments, and the synaptic responses were completely abolished.

Figure 3. NMDA synaptic responses are larger in H-ras(−/−) mice. a, AMPA receptor-mediated EPSCs (downward traces) and NMDA receptor-mediated EPSCs (upward traces) were recorded at membrane potentials of −90 and +40 mV, respectively. When NMDA EPSCs were recorded, 10 μM CNQX was present to block AMPA EPSCs. b, The ratio of amplitudes of the NMDA EPSC to those of the AMPA EPSC was calculated for each cell, and the values were then averaged for all cells. The ratio was significantly larger in H-ras(−/−) mice than in wild-type mice (p < 0.02). c, The current–voltage relationships of NMDA synaptic currents in wild-type (open circles; n = 9 cells, 5 mice) and H-ras(−/−) (filled circles; n = 7 cells, 4 mice) mice. Current amplitudes, which were larger in H-ras(−/−) mice, were normalized to the value obtained at +40 mV for easier comparison. d, The input–output relationships of AMPA EPSCs of wild-type (open circles; n = 10 slices, 5 mice) and H-ras(−/−) (filled circles; n = 10 slices, 5 mice) mice. Sample traces in the inset represent the responses evoked with five different stimulus intensities varying from 1.35 to 1.71 V. e, The input–output relationships of NMDA EPSCs of wild-type (open circles; n = 14 slices, 7 mice) and H-ras(−/−) (filled circles; n = 14 slices, 7 mice) mice. CNQX (10 μM) was present to block AMPA receptor-mediated synaptic responses. Sample traces in the inset represent the responses evoked with five different stimulus intensities varying from 2.16 to 2.88 V. Stimulation with higher intensities was used to overcome the Mg2+ block of the NMDA receptor. As shown in the inset, in H-ras(−/−) mice, NMDA EPSCs were often accompanied by bursting activity, presumably because of their large size. In some experiments, 40 μM t-APV was applied at the end of the experiments, and the synaptic responses were completely abolished.

The enhanced NMDA synaptic responses could be introduced by changes in the biophysical properties of the receptor. However, the rise time (wild type, 13.5 ± 0.3 msec, n = 13 cells and 7 mice; H-ras(−/−), 13.1 ± 0.4 msec, n = 12 cells and 6 mice;
It is well established that the induction of LTP at the Schaffer collateral–commissural-CA1 synapse is mediated by the activation of postsynaptic NMDA receptors (Collingridge et al., 1983; Nicoll and Malenka, 1995). EPSPs were recorded in the CA1 region using extracellular field potential recording techniques. The stimulation of afferent fibers evoked AMPA receptor-mediated EPSPs in the stratum radiatum. The tetanic stimulation of the afferent fibers (100 Hz for 1 sec, repeated twice at a 10 sec interval) gave rise to LTP of excitatory synaptic transmission in wild-type mice (Fig. 4a,b). The magnitude of LTP in the H-ras(−/−) mice induced by the same conditioning was remarkably larger than that in the wild-type mice (Fig. 4a,b). The induction of LTP in the H-ras(−/−) mice was completely blocked by the NMDA receptor antagonist D-2-amino-5-phosphonovaleric acid (D-APV) (50 μM; n = 2 slices and 1 mouse), indicating that the increased magnitude of LTP was not caused by the addition of NMDA receptor. It is thus possible that the enhanced synaptic NMDA responses in H-ras(−/−) mice are associated with an increase in the single channel conductance of the existing receptor channel and/or an increase in the number of active NMDA receptor channels.

Enhanced LTP in H-ras-deficient mice

The larger magnitude LTP in H-ras(−/−) mice is most likely attributable to the enhanced NMDA receptor activity, it is also possible that a change in the presynaptic transmitter release probability may be involved in the modulation of LTP. We thus examined the paired-pulse facilitation (PPF) (Zucker, 1989; Manabe et al., 1993) of AMPA receptor-mediated EPSCs to assess whether H-ras knock-out may affect the presynaptic release mechanisms. PPF induced at an interstimulus interval of 50 msec was not significantly different (p > 0.3) between wild-type (1.85 ± 0.06, n = 18 cells and 9 mice) and H-ras(−/−) (1.89 ± 0.08, n = 12 cells and 6 mice) mice (Fig. 5a,b), suggesting that presynaptic release probability is not affected by H-Ras proteins.

The data presented above strongly suggest that the enhanced LTP in H-ras(−/−) mice results from the larger synaptic NMDA responses. If the enhanced LTP is solely a result of an increased Ca2+ influx through the NMDA receptors and not a result of a modification of LTP expression mechanisms, then the LTP saturation level of the H-ras(−/−) mice should be similar to that of the wild-type mice. To saturate LTP, high-frequency stimulation was repeatedly applied until there was no more potentiation (Fig. 5c). The saturation level of H-ras(−/−) slices (229.8 ± 15.6% of control, n = 4 slices and 4 mice) was not significantly different (p > 0.3) (Fig. 5d) from that of wild-type slices (222.3 ± 21.1%, n = 4 slices and 4 mice), suggesting that the expression mechanisms are unchanged. Because many reports suggest that LTP is expressed, at least in part, by an increase in AMPA receptor sensitivity (Davies et al., 1989; Manabe et al., 1992; Manabe and Nicoll, 1994; Isaac et al., 1995; Liao et al., 1995), the larger magnitude of LTP could be explained by a downregulation of the AMPA receptor in naive slices from the H-ras(−/−) mice, which could also account for the higher ratio of NMDA/AMPA synaptic responses (Fig. 3a,b). However, the results of the LTP saturation experiments, together with those of the experiments examining the input–output relationships of AMPA responses (Fig. 5d), rule out this possibility, because the saturation level of LTP in the H-ras(−/−) mice should be higher than that in the wild-type mice if the basal level of AMPA sensitivity in H-ras(−/−) mice is lower. It is thus unlikely that the enhanced LTP in H-ras(−/−) mice is attributable to a downregulation of the AMPA receptor sensitivity, thus further supporting the se-

**Figure 4.** LTP is enhanced in H-ras(−/−) mice. a, Sample traces of field EPSPs (average of 10 consecutive responses) of wild-type and H-ras(−/−) mice recorded at the times indicated in b. The stimulus artifacts are truncated. b, The averaged time course of LTP in wild-type (n = 13 slices, 10 mice) and H-ras(−/−) (n = 16 slices, 12 mice) mice. Initial EPSP slopes were measured, and the values were normalized in each experiment using the averaged slope value measured during the control period (time, −30 to 0 min). Tetanic stimulation was applied at time 0. c, Depolarization caused by high-frequency stimulation (100 Hz for 1 sec) in the presence of 50 μM D-APV and after washout of the antagonist. The stimulus strength was adjusted to evoke an EPSP that had an initial slope value of 0.16 to 0.18 mV/msec, thus the depolarization in the presence of APV was similar between the wild-type and H-ras(−/−) mice. The stimulus artifacts are truncated. d, Depolarization at 150 msec from the beginning of tetanic stimulation was measured in the presence of 50 μM D-APV and then 20 min after washout of the antagonist. NMDA receptor-dependent depolarization was calculated by subtracting the value in APV from that after washout, which included both NMDA and AMPA receptor-activated depolarization. In the presence of APV, depolarization solely mediated by AMPA receptors was recorded. NMDA receptor-dependent depolarization was calculated by subtracting AMPA receptor-dependent depolarization from the total depolarization in the absence of APV. The ratio of NMDA to AMPA receptor-dependent depolarization was significantly larger (p < 0.04) in the H-ras(−/−) than in wild-type mice.
shown normal NMDA synaptic responses, the mechanism of the enhancement of LTP in our H-ras\(^{–/-}\) mice is different from those in the nociception receptor- and PSD-95-deficient mice. Furthermore, we confirm that the amount of PSD-95 in the NMDA receptor complex coimmunoprecipitated with an anti-NR1 antibody is not significantly changed in H-ras\(^{–/-}\) mice, suggesting that the increase in LTP produced by loss of H-Ras does not involve a decrease in PSD-95 expression.

We found that the tyrosine phosphorylation of NR2A and NR2B subunits of NMDA receptors was increased in the H-ras\(^{–/-}\) hippocampus. The NMDA synaptic responses were increased in baseline synaptic transmission, as well as during tetanic stimulation. The potentiated NMDA synaptic response is probably attributable to the increase in tyrosine phosphorylation of the post synaptic receptors in the mutant mice, because the tyrosine phosphorylation of NMDA receptors is reported to enhance the activity of NMDA receptor (Wang and Salter, 1994; Yu et al., 1997). Thus, the regulation of synaptic plasticity via its regulation of the NMDA receptor phosphorylation in the adult CNS may be a novel H-Ras function. The signal transduction pathway from H-Ras proteins to NMDA receptors remains to be elucidated. It has been shown that PTKs, such as Src family kinases, exist upstream of Ras in signal transduction and positively regulate Ras activities (Sadoshima and Izumo, 1996). Our results suggest that the Ras protein inhibits the PTK activities on NMDA receptors by an unknown pathway.

We, however, could not exclude the possibility that upregulation of NMDA synaptic responses and enhancement of LTP in H-ras\(^{–/-}\) mice might be caused indirectly by an impairment in neuronal development but not directly by the lack of H-Ras in adult hippocampal neurons, because H-Ras proteins have been shown to play a critical role in the proliferation and development in a variety of cell types and at different developmental stages. In that case, upregulation of tyrosine phosphorylation of NMDA receptors might be caused by the absence of H-Ras during development but not by the deficiency of H-Ras-mediated pathways acutely activated by the extracellular signals in the adult hippocampus. In addition, H-ras\(^{–/-}\) hippocampus might have morphological changes on the subcellular level, such as increase of dendritic spines expressing NMDA receptors but not AMPA receptors, although we could not find a significant morphological abnormality in H-ras\(^{–/-}\) brain, including the hippocampus. Furthermore, the larger depolarization and enhancement of LTP could be explained by the modification of voltage-dependent channels in the H-ras\(^{–/-}\) mice. However, we did not observe any difference between the wild-type and H-ras\(^{–/-}\) mice in the depolarization during the tetanus in the presence of APV (Fig. 4c), suggesting that the voltage-dependent component may not be modulated by the mutation. Even in the presence of APV, the depolarization during tetanus is very large, which should activate voltage-dependent channels considerably. Thus, it is rather unlikely that the modulation of voltage-dependent channels is the primary cause of the enhancement of LTP.

Ras proteins are activated by GEFs, which promote the exchange of bound GDP for GTP, and inactivated by GAPs, which stimulate the intrinsic Ras GTPase activity. Ras GEFs include Ras-GRF (CDC25\(^{Mm}\)) (Martegani et al., 1992; Shou et al., 1992) and Ras-GRF2 (Fam et al., 1997), mSOS1 and mSOS (Bowtell et al., 1992; Chardin et al., 1993), Ras-GRP (calcium- and diacylglycerol-regulated GEFII) (Ebinu et al., 1998; Kawasaki et al., 1991), and SmgGDS (Mizuno et al., 1998). Of these, mice lacking Ras-GRF showed normal LTP, although the analysis on

**DISCUSSION**

The NMDA receptor channel plays a central role in the development (McDonald and Johnston, 1990), plasticity (Malenka and Nicoll, 1993), and neurotoxicity (Choi, 1988) in the CNS. The essential role of NMDA receptors in synaptic plasticity, in particular in the CA1 region of the hippocampus, has been described by many researchers (Malenka and Nicoll, 1993). When NMDA receptor activation is blocked by an antagonist, LTP induced by standard procedures is inhibited (Collingridge et al., 1983). The knockout of one of the NMDA receptor subunits, NR2A, causes a reduction in the NMDA synaptic responses in the CA1 region, resulting in a decrease in the magnitude of LTP (Sakimura et al., 1995). Furthermore, a partial blockade of NMDA receptor activity results in no change or, in some cases, in long-term depression of synaptic transmission, depending on the degree of the blockade (Cummings et al., 1996). However, it is unknown as to whether LTP is enhanced when the NMDA responses are increased. In our present study, NMDA synaptic responses were selectively enhanced without apparent changes in the presynaptic release probability in H-ras\(^{–/-}\) mice, thus enabling us to examine the effect of a selective enhancement of NMDA receptor activity on LTP induction. Recently, two kinds of knock-out mice, the nociceptin receptor-deficient mice (Manabe et al., 1998) and the PSD-95-deficient mice (Migaud et al., 1998), have been reported to show an enhancement of LTP. Because both knock-out mice

**Figure 5.** The LTP modulation is not mediated by a change in presynaptic release mechanisms but by a change in the postsynaptic induction mechanism. a, PPF of synaptic responses was induced by delivering afferent fiber stimulation twice at an interstimulus interval of 50 msec. Cells were voltage-clamped at \(-90\) mV. b, Averaged values of PPF. The facilitation ratios were calculated by dividing the amplitude of the second EPSC’s by that of the first EPSC’s. Ten consecutive traces were averaged, and the amplitude of the averaged trace was measured. c, No significant difference in PPF between the wild-type and H-ras\(^{–/-}\) mice. d, Summary of LTP saturation measurements. There was no significant difference between the two groups.
properties of basal synaptic transmission revealed that Ras-GRF(−/−) mice showed larger EPSPs in the CA1 region of the hippocampus (Brambilla et al., 1997). On the other hand, in our H-ras(−/−) mice, LTP is enhanced, but basal synaptic transmission mediated by AMPA receptors is not changed. Ras-GRF specifically activates H-Ras proteins among three mammalian Ras proteins in vivo (Jones and Jackson, 1998). Although the Ras activity was not measured in the Ras-GRF(−/−) mice, it is possible that, in the Ras-GRF(−/−) mice, the H-Ras activity was not reduced because of the compensation of other Ras GEFs existing in the hippocampus. In that case, the electrophysiological phenotype in the Ras-GRF(−/−) mice could be attributable to downregulation of other target molecules of Ras-GRF. In the RasGAP family, recently cloned SynGAP exists in the PSD fraction and is included in the NMDA receptor complex (Chen et al., 1998; Kim et al., 1998), suggesting the involvement of Ras proteins in the NMDA receptor regulation.

Although Ras proteins have been implicated in cell proliferation and differentiation, and thus in the cellular functions that are critical for the development of the organism, our present study revealed a novel link between the H-Ras protein and the NMDA receptor via the Ras pathway. Because the NMDA receptor plays a central role in the modulation of synaptic transmission in the CNS and learning and memory, the regulation of activity-dependent synaptic plasticity and learning and memory in adult animals may be another major and pivotal role for Ras proteins.
