Neuronal Apoptosis Associated with Morphine Tolerance: Evidence for an Opioid-Induced Neurotoxic Mechanism

Jianren Mao, Backil Sung, Ru-Rong Ji, and Grewo Lim

Massachusetts General Hospital Pain Center and Neural Plasticity Research Group, Department of Anesthesia and Critical Care, Massachusetts General Hospital, Harvard Medical School, Boston, Massachusetts 02114

Tolerance to the analgesic effect of an opioid is a pharmacological phenomenon that occurs after its prolonged administration. Activation of the NMDA receptor (NMDAR) has been implicated in the cellular mechanisms of opioid tolerance. However, activation of NMDARs can lead to neurotoxicity under many circumstances. Here we demonstrate that spinal neuronal apoptosis was induced in rats made tolerant to morphine administered through intrathecal boluses or continuous infusion. The apoptotic cells were predominantly located in the superficial spinal cord dorsal horn, and most apoptotic cells also expressed glutamic acid decarboxylase, a key enzyme for the synthesis of the inhibitory neurotransmitter GABA. Consistently, increased nociceptive sensitivity to heat stimulation was observed in these same rats. Mechanistically, the spinal glutamatergic activity modulated morphine-induced neuronal apoptosis, because pharmacological perturbation of the spinal glutamate transporter activity or coadministration of morphine with the NMDAR antagonist (+)-5-methyl-10,11-dihydro-5H-dibenzo[a,d]cyclohepten-5,10-imine maleate affected both morphine tolerance and neuronal apoptosis. At the intracellular level, prolonged morphine administration resulted in an upregulation of the proapoptotic caspase-3 and Bax proteins but a downregulation of the antiapoptotic Bcl-2 protein in the spinal cord dorsal horn. Furthermore, coadministration with morphine of N-benzylxycarbonyl-Val-Ala-Asp-fluoromethyl ketone (a pan-caspase inhibitor) or acetyl-aspartyl-glutamyl-valyl-aspart-1-aldehyde (a relatively selective caspase-3 inhibitor) blocked morphine-induced neuronal apoptosis. Blockade of the spinal caspase-like activity also partially prevented morphine tolerance and the associated increase in nociceptive sensitivity. These results indicate an opioid-induced neurotoxic consequence regulated by the NMDAR–caspase pathway, a mechanism that may have clinical implications in opioid therapy and substance abuse.

Key words: apoptosis; opioid tolerance; analgesia; NMDA; glutamate transporter; caspase-3; Bax; Bcl-2

Opioids are a class of powerful analgesics that are commonly used in acute and chronic pain management. Prolonged exposure to an opioid results in the development of analgesic tolerance, which significantly hampers the clinical utility of opioids necessitating repeated dose escalation regardless of disease progression. As such, the cellular and molecular mechanisms of opioid tolerance have been a focus of extensive research interest. Over a decade, the NMDA receptor (NMDAR), a subgroup of glutamate receptors, has been implicated in the development of opioid tolerance, particularly µ-opioid tolerance (Marek et al. 1991a,b; Trujillo and Akil, 1991; Elliott et al., 1994; Mao et al., 1994). Although the mechanisms of NMDAR involvement in opioid analgesic tolerance remain unclear, Ca$^{2+}$-regulated intracellular protein kinase C (PKC) is likely to be a link in this process (Mao et al., 1994, 1995c; Mayer et al., 1995; Narita et al., 1996, 2001; Zeitz et al., 2002). PKC may directly or indirectly regulate the activity of NMDARs by removing the Mg$^{2+}$ blockade from the NMDAR–Ca$^{2+}$ channel site (Chen and Huang, 1992; Woof and Salter, 2000), regulating NMDAR trafficking and gating (Lan et al., 2001), or both. Thus, NMDARs could become involved in the cellular mechanisms of opioid tolerance after prolonged administration of an opioid such as morphine (Trujillo and Akil, 1991; Mao, 1999).

Activation of NMDARs can lead to neurotoxicity under many circumstances (Rothman and Olney, 1986; Swan and Meldrum, 1990; Moncada et al., 1992; Catania et al., 1993). For instance, peripheral nerve injury has been shown to activate spinal cord NMDARs, which results in not only intractable neuropathic pain but also neuronal cell death by means of apoptosis (Mao et al. 1992b, 1997; Kawamura et al., 1997; Whiteside and Munglani, 2001). Furthermore, cross talk between the cellular mechanisms of opioid tolerance and neuropathic pain has been proposed, suggesting that a common cellular mechanism may be involved in both neuropathic pain and opioid tolerance (Mao et al. 1995b; Mayer et al., 1999). Thus, it is possible that the cellular process leading to the development of opioid tolerance may also cause neurotoxic changes in response to prolonged opioid administration. Here we examined the hypothesis that neurotoxicity in the form of apoptotic cell death would be induced in association with the development of morphine tolerance.

At the synaptic level, glutamate, an endogenous ligand for the NMDAR, is actively and tightly regulated by the glutamate transporter (GT) system (Robinson and Dowd, 1997; Semba and Wakuta, 1998; Jabaoud et al., 2000). Indeed, the expression of GLT-1 (a glial GT) has been shown to be reduced after exposure to opioids in both cortical cell cultures (Thorlin et al., 1998) and brain regions (Ozawa et al., 2001), which may influence the development of morphine tolerance and dependence (Nakagawa et al., 2001). At the intracellular level, glutamate-induced neuro-
nal apoptosis has been shown to be modulated by common intracellular regulators of apoptosis, including Bax, Bcl-2, and caspases (Du et al., 1997; Tenneti et al., 1998; Allen et al., 1999; Springer et al., 1999; Kwong and Lam, 2000; Nath et al., 2000; Puka-Sundvall et al., 2000; Qin et al., 2000; Tenneti and Lipton, 2000; Bachis et al., 2001; Chan et al., 2001). Thus, if prolonged exposure to an opioid induces apoptosis that is regulated through NMDAR-mediated glutamate neurotoxicity, one would expect to see the modulation of opioid-induced apoptosis by spinal GTs and NMDARs as well as by common intracellular regulators of apoptosis such as caspases. These possibilities were examined in the present study to investigate the cellular mechanisms of neuronal apoptosis associated with the development of morphine tolerance.

MATERIALS AND METHODS

Experimental animals

Adult male Sprague Dawley rats (Charles River Laboratories, Wilmington, MA) weighing 300–350 g were used. Animals were housed in cages with water and food pellets available ad libitum. The animal room was artificially illuminated from 7 A.M. to 7 P.M. The experimental protocol was approved by our Institutional Animal Care and Use Committee.

Intrathecal catheter and osmotic pump implantation

An intrathecal PE 10 catheter was implanted in each rat according to a previously published method (Yaksh and Rudy, 1976). Those animals that exhibited neurological deficits after intrathecal catheter implantation were excluded from the experiments. Drugs were delivered via an intrathecal catheter in a total volume of 10 μl followed by a saline flush. The following drugs were purchased from Sigma (St. Louis, MO): (+)-5-methyl-10,11-dihydro-5H-dibenzo [a,d] cycloheptene-5,10-imine maleate (MK-801), morphine, riluzole, l-trans-pyrrolidine-2-4-dicarboxylate (PDC), N-benzyloxycarbonyl-Val-Ala-Asp-fluoromethyl ketone (Z-VAD-FMK), and acetyl-aspartyl-glutamyl-valyl-aspartyl-aldehyde (AC-DEVD-CHO).

For continuous intrathecal infusion, osmotic minipumps (Alza, Mountain View, CA) were used as described previously (Granados-Soto et al., 2000; Vanderah et al., 2000). An osmotic pump, placed in a subcutaneous space after a surgical procedure, was connected to an intrathecal catheter via a piece of PE 60 catheter. The filled minipumps were soaked in normal saline for 4 hr before the insertion to ensure immediate drug delivery. The integrity of the pump delivery system was reexamined at the end of each experiment when the spinal cords were harvested.

Induction of morphine tolerance and behavioral test

Tolerance to the antinociceptive effect of morphine was induced using previously published method (Yaksh and Rudy, 1976). Those animals were divided into two treatment regimens: repeated bolus and continuous infusion. Morphine was given twice daily for 7 days in the repeated bolus regimen, whereas continuous morphine infusion was made for 7 d via an implanted osmotic pump system delivering at 1 μl/hr for 7 d. Differences in morphine antinociception among treatment groups were assessed on day 8 by the tail flick test at 30 min after a probe dose of either 10 μg of morphine (intrathecal) for repeated bolus groups or 5 mg/kg morphine (intraperitoneal) for continuous infusion groups. Additionally, foot withdrawal latencies were compared among groups between day 0 (baseline) and the last day (day 8) of the experimental period to determine whether morphine-tolerant rats would develop increased sensitivity to noxious heat stimulation as shown in previous studies (Mao et al. 1995a; Ossipov et al., 1995; Vanderah et al., 2000). Because the osmotic pump infusion began on day 1, day 8 was the last day of a full 7 d delivery using an osmotic pump.

The routine tail flick test was made with baseline latencies of 4–5 sec and a cutoff time of 10 sec (D’Amour and Smith, 1941; Akil and Mayer, 1972). Three trials were made with an intertrial interval of 1 min and with changes of the tail position receiving radiant heat stimulation at each trial. The percent maximal possible antinociceptive effect (%MPAE) was determined by comparing the tail flick latency before baseline (BL) and after a drug injection (TL) using the equation %MPAE = [(TL – BL)/(10 – BL)] × 100 (the constant 10 refers to the cutoff time). To examine changes in baseline nociceptive responses before and after a prolonged morphine administration, the foot withdrawal test with baseline latencies of 9–11 sec and a cutoff time of 20 sec was used as described previously (Hargreaves et al., 1988). The foot withdrawal test was used because this test has been shown to be sensitive in detecting moderate changes in baseline nociceptive responses (Mao et al., 1994).

In situ terminal deoxynucleotidyl transferase-mediated biotinylated UTP nick end-labeling staining

The DNA fragmentation indicative of apoptosis can be demonstrated using several methods, including terminal deoxynucleotidyl transferase-mediated biotinylated UTP nick end labeling (TUNEL), gel electrophoresis, and in situ nick translation (Gavrieli et al., 1992; Baba et al., 1999). In this study, we used the TUNEL method because this method allows us to examine the topographic distribution of apoptotic cells within the spinal cord dorsal horn, which cannot be shown using gel electrophoresis. Besides, it has been shown that apoptotic changes revealed by the TUNEL method are consistent with the gel electrophoresis data under several experimental conditions (Gavrieli et al., 1992; Lo et al., 1995). As described below, both positive and negative controls were included in the staining process and the costaining with Hoechst (for the in vivo detection of DNA), and TUNEL was used to ensure the consistency of the data collection. In addition, the morphology of TUNEL- and Hoechst-stained nuclei also was examined under a high-magnification fluorescent microscope to identify features of apoptotic cells (e.g., condensed DNA segments and nuclear fragmentation).

A modified TUNEL staining protocol described in previous studies was followed (Gavrieli et al., 1992; Hara et al., 1995, 1998). Spinal cords from each group were collected after the final behavioral test on day 8 after transcutaneous perfusion with saline and a fixative containing 4% paraformaldehyde and cut into 10-μm-thick sections with a cryostat. One of every five such sections was mounted on a precleaned slide. The TUNEL staining was performed using the apoptosis detection kit purchased from Roche Molecular Biochemicals (Indianapolis, IN). Briefly, the sections were first incubated in a solution containing 0.1% Triton X-100 and 0.1% sodium citrate for 2 min on ice (4°C) to increase the permeability. After being washed twice in PBS, pH 7.4, the sections were immersed in the TUNEL reaction mixture, containing biotinylated dUTP and terminal deoxynucleotidyl transferase (TdT) conjugated with fluorochromes (tetramethylrhodamine red) for 60 min at 37°C in a dark, humidified atmosphere. The process was terminated by washing the sections twice in a blocking buffer (PBS, Triton X-100, and BSA). In each assay, negative controls were included using the same incubation procedure but omitting TdT in the process, whereas positive controls were performed by incubating the permeated sections with DNase (1 μg/ml) to induce DNA strand breakage.

Immunocytochemical and Hoechst staining

Routine immunocytochemical staining (Ji et al., 1995) was used to detect neuronal-specific nuclear protein (NeuN) (1:500, a marker for neuronal nuclear protein; Mullen et al., 1992), glutamic acid decarboxylase 67 (GAD67; 1:1000), Bax (1:250), caspase-3 (1:500), and cleaved caspase-3 (1:500). All antibodies were purchased from Chemicon (Temecula, CA) except for the cleaved caspase-3 antibody (Cell Signaling Technology, Beverly, MA). The process of harvesting, fixing, and slicing spinal cord samples was the same as that used for the TUNEL procedure. After the TUNEL staining, sections were blocked with 1% goat serum in 0.3% Triton X-100 for 1 hr at room temperature and incubated overnight at 4°C with a primary antibody. The sections were then incubated for 1 hr at room temperature with a primary antibody conjugated secondary antibody (1:300; Chemicon). The Hoechst staining (Hoechst 33342) was used for the in vivo detection of DNA in spinal sections. Colocalization of TUNEL with NeuN, GAD67, caspase-3, Bax, or Hoechst staining was examined by an imaging program (Adobe Photoshop).

Cell counting

Five or six sections randomly selected from each animal were analyzed by using a fluorescence microscope linked to a digital camera. Numbers of apoptotic cells were counted in a blinded manner for both sides of each spinal section, in which three regions (laminas I–II, III–IV, and V–VI) were divided based on the laminar delineation described previously (Molander et al., 1984; Mao et al. 1992a, 1993). These regions were chosen because they represent functional subdivisions of the spinal cord dorsal horn (Price, 1988). Two approaches were used to display these
laminar divisions. Spinal sections were either counterstained with Nissl staining or stained with NeuN staining. Both methods have been commonly used to outline spinal cord dorsal horn divisions based on distinct laminar patterns described by Molander et al. (1984). Because the TUNEL staining is only visible in the cell body, and sections selected for the analysis were chosen from at least 50 μm apart (see above), this analysis avoided double counting the number of apoptotic cells. To analyze sections with costainings (e.g., TUNEL and caspase-3), images from each staining were digitized and then merged using an imaging program (Adobe) to examine the presence of colocalization.

Western analysis of Bax, Bcl-2, and caspase-3
For Western blotting, rats were rapidly (<1 min) killed in a CO2 chamber, and the dorsal horns of the lumbar spinal cord segments were removed and homogenized in SDS sample buffer containing a mixture of proteinase inhibitors (Sigma). The lumbar segments were harvested because an intrathecal catheter was aimed to deliver drugs at this site. Protein samples were separated on an SDS-PAGE gel (4–15% gradient gel; Bio-Rad, Hercules, CA) and transferred to polyvinylidene difluoride filters (Millipore, Bedford, MA). The filters were blocked with 3% milk and incubated overnight at 4°C with a primary antibody (Bax, 1:100; caspase-3, 1:1000 for 19 and 32 kDa; and Bcl-2, 1:5000) and 1 hr at room temperature with a horseradish peroxidase-conjugated secondary antibody (1:5000; Amersham Biosciences, Arlington Heights, IL). The blots were then visualized in ECL solution (PerkinElmer Life Sciences, Emeryville, CA) for 1 min and exposed onto hyperfilms (Amersham) for 1–10 min. The gray density of each blot was obtained for each experimental group. The same amounts of protein for each loading lane were estimated by the Bio-Rad protein assay, and the extracellular signal-regulated kinase (ERK) protein was used as a loading control.

Experimental design
Experiment 1: induction of apoptosis after morphine tolerance. Seven groups of rats were used in this experiment. To investigate whether repeated exposure to morphine boluses would result in the induction of apoptosis, three groups of rats (n = 5) were given each 10 or 20 μg of intrathecal morphine or saline twice daily for 7 d. In addition, three more groups of rats (n = 5) were infused, via an intrathecal osmotic pump for 7 d, with 10 or 20 nmol · µl⁻1 · hr⁻1 morphine or saline to determine whether apoptosis would be induced using continuous infusion. This treatment regimen was included because repeated morphine boluses have been suggested to cause intermittent opioid withdrawals, a process that could increase NMDAR activity via glutamate release independent of the intracellular mechanisms of opioid tolerance (Ibuki et al., 1997; Dunham and Pulai, 1998). In either treatment regimen, morphine doses were chosen on the basis of the previous studies that showed the development of morphine tolerance using these doses (Mao et al., 1994; Ibuki et al., 1997). An additional group of rats (n = 4) was included to examine whether apoptosis occurred in response to an acute morphine effect after a single intrathecal injection of 20 μg of morphine. In all groups, spinal cords were harvested after the final behavioral test as described above.

To investigate the neurochemical nature of apoptotic cells, the spinal sections were examined for the colocalization of TUNEL and GAD, a key enzyme for the synthesis of the inhibitory neurotransmitter GABA. Furthermore, neuronal apoptosis was identified by examining the colocalization of TUNEL and NeuN as described above.

Experiment 2: role of the spinal GT and NMDAR in morphine-induced apoptosis. To investigate whether perturbation of spinal GT activity would affect opioid-induced apoptosis, PDC, a GT inhibitor (Lievens et al., 2000; Matthews et al., 2000), and riluzole, a positive GT regulator (Azbill et al., 2000), were used in this set of experiments. Although riluzole was initially considered as an inhibitor of the presynaptic glutamate release (Cheramy et al., 1992; Doble, 1996), this agent has been shown recently to be a positive GT regulator that increases glutamate uptake in synaptosomes under both in vivo and in vitro conditions (Azbill et al., 2000). Four groups of rats (n = 5) were used, including (1) 10 μg of morphine plus 20 μg of riluzole, (2) 20 μg of riluzole alone, (3) 10 μg of morphine plus 20 μg of PDC, and (4) 20 μg of PDC alone. The drugs or their combinations were given intrathecally twice daily for 7 d and these groups were compared with those receiving 10 μg of morphine or saline alone in identical conditions. The dose for riluzole or PDC was selected on the basis of a pilot study showing a reliable effect of each agent at this dose on modulating the development of morphine (10 μg, intrathecal) tolerance. In addition, the equivalent doses of PDC and riluzole have been shown to be effective in regulating the extracellular glutamate concentration and NMDAR-mediated activity under both in vivo and in vitro experimental conditions (Semba and Wakuta, 1998; Azbill et al., 2000; Jabaudon et al., 2000; Lievens et al., 2000; Matthews et al., 2000).

To determine the role of NMDARs in the induction of neuronal apoptosis, two more groups of rats each received a 7 d intrathecal infusion with either 20 nmol · µl⁻¹ · hr⁻¹ morphine plus 1 nmol · µl⁻¹ · hr⁻¹ MK-801 (n = 9) or 1 nmol · µl⁻¹ · hr⁻¹ MK-801 alone (n = 6). The dose for MK-801 was selected on the basis of a previous study showing the blockade of morphine tolerance by this dose of MK-801 (Ibuki et al., 1997). The data from these groups were compared with those from the 20 nmol · µl⁻¹ · hr⁻¹ morphine- or saline-alone groups in experiment 1.

Experiment 3: role of intracellular apoptosis regulators in morphine-induced apoptosis. To examine the intracellular mechanisms of morphine-induced apoptosis, two approaches were used. First, changes in Bax, caspase-3, and Bcl-2 were examined using the methods of Western blotting and immunocytochemistry in rats receiving either 20 μg of morphine or saline (n = 8–10 per group for separate sample collections) twice daily for 7 d. Second, additional groups of rats (n = 4–6 per group) were used to examine whether blockade of caspases including caspase-3 would prevent morphine-induced apoptosis. Thus, each group of rats received intrathecal (1) saline, (2) 20 μg of morphine plus vehicle, (3) 20 μg of morphine plus 5 μg of Z-VDAD-FMK (a pan-caspase inhibitor), or (4) 20 μg of morphine plus 5 μg of AC-DEVD-CHO (a relatively selective caspase-3 inhibitor) twice daily for 7 d. The selected dose for each agent was based on previous studies showing a reliable inhibition of the caspase-like activity in vivo within this intrathecal dose range (Qin et al., 2000; Tamyan et al., 2001). For additional controls, rats (n = 3–4 per group) received 7 d intrathecal treatment (twice daily) with the same dose of Z-VDAD-FMK or AC-DEVD-CHO alone. A single dose of 10 μg of morphine was given on day 8 to examine whether Z-VDAD-FMK or AC-DEVD-CHO alone would affect morphine-induced antinociception.

Statistical analysis
Data obtained from the tail flick test were first calculated to yield the mean ± S.E.M. as shown previously (Mao et al., 1994). The data were then analyzed by using two-way ANOVA to detect overall differences among treatment groups. When significant main effects were observed, Waller-Duncan (WD) K ratio t tests (WD) were performed to determine sources of differences. The histological data (cell counting) from each spinal section were first averaged for each dorsal horn region and then analyzed using ANOVA followed by the WD test to determine the statistical differences. Paired Student’s t test was used to examine statistical differences in the gray density of Western blots.

RESULTS
Induction of neuronal apoptosis associated with morphine tolerance
Twice daily administration of 10 or 20 μg of morphine for 7 d produced, dose-dependently, tolerance to the antinociceptive effect of morphine when tested on day 8 (Fig. 1A) (< 0.01). This morphine treatment regimen induced apoptotic cells within the spinal cord dorsal horn of the same rats (Fig. 2). The in situ detection of DNA fragmentation by the TUNEL method was further indicated by the colocalization of both TUNEL and Hoechst (detecting in situ DNA) staining in the same cells (Fig. 2D–F). Moreover, features of apoptotic cells were observed in the TUNEL and Hoechst stained nuclei including nuclear fragmentation and condensed DNA segments (Fig. 2D–F). In contrast, apoptotic cells were hardly detectable in saline-treated rats (Figs. 2A, 3A) (< 0.01), indicating that the induction of apoptosis is specifically associated with morphine treatment. Likewise, few apoptotic cells were present in rats receiving a single intrathecal treatment of 20 μg of morphine (Fig. 3A) (< 0.05), indicating that the induction of apoptosis is not attributable to an acute morphine effect.

Similar to the results obtained using the bolus treatment regimen, tolerance to the morphine antinociception developed dose-dependently when tested on day 8 in rats receiving 10 or 20
compared with the corresponding saline group; morphine- but not saline-infused rats (Fig. 3A). Similarly, %MPAE in response to 5 mg/kg morphine (intraperitoneally) on day 8 was reduced in rats receiving a 7 d infusion, via an intrathecal osmotic pump, with 10 or 20 nmol·µl⁻¹·hr⁻¹ morphine (C10, C20). In both treatment regimens, the development of morphine tolerance was dose-dependent. B, MK-801 (1 nmol·µl⁻¹·hr⁻¹) blocked the development of tolerance when given with morphine (20 nmol·µl⁻¹·hr⁻¹) for 7 d (C20+MK). Twice daily coadministration of 10 µg of morphine and 20 µg of PDC (a GT inhibitor; B10+P) for 7 d potentiated, whereas combined 10 µg of morphine and 20 µg of riluzole (a positive GT regulator; B10+R) reduced, the development of morphine tolerance when tested on day 8 with a probe dose of 20 µg of morphine (intrathecal). *p < 0.05; **p < 0.01 compared with the corresponding saline group; *p < 0.05 compared with the corresponding low-dose morphine group (A) or the morphine-alone group (B).

Figure 1. Modulation of morphine tolerance by regulating spinal GT and NMDAR activity. A, When tested on day 8, %MPAE in response to 20 µg of intrathecal morphine was reduced in rats treated with 10 or 20 µg of intrathecal morphine (B10, B20) twice daily for 7 d. Similarly, %MPAE in response to 5 mg/kg morphine (intraperitoneally) on day 8 was reduced in rats receiving 7 d infusion, via an intrathecal osmotic pump, with 10 or 20 nmol·µl⁻¹·hr⁻¹ morphine (C10, C20). In both treatment regimens, the development of morphine tolerance was dose-dependent. B, MK-801 (1 nmol·µl⁻¹·hr⁻¹) blocked the development of tolerance when given with morphine (20 nmol·µl⁻¹·hr⁻¹) for 7 d (C20+MK). Twice daily coadministration of 10 µg of morphine and 20 µg of PDC (a GT inhibitor; B10+P) for 7 d potentiated, whereas combined 10 µg of morphine and 20 µg of riluzole (a positive GT regulator; B10+R) reduced, the development of morphine tolerance when tested on day 8 with a probe dose of 20 µg of morphine (intrathecal). *p < 0.05; **p < 0.01 compared with the corresponding saline group; *p < 0.05 compared with the corresponding low-dose morphine group (A) or the morphine-alone group (B).

nmol·µl⁻¹·hr⁻¹ morphine, but not saline, infusion for 7 d (Fig. 1A) (p < 0.01). Consistently, apoptotic cells were observed in morphine- but not saline-infused rats (Fig. 3A) (p < 0.01). Both the distribution and quantity of apoptotic cells were comparable with those seen in rats treated with morphine boluses (Fig. 3A). In both experiments, more apoptotic cells were observed in rats receiving a high dose (20 µg or 20 nmol·µl⁻¹·hr⁻¹) than a low dose (10 µg or 10 nmol·µl⁻¹·hr⁻¹) of morphine (Fig. 3A) (p < 0.05), indicating that the induction of apoptosis was dose-dependent.

Topographically, these apoptotic cells were primarily located in laminae I–II of the spinal cord dorsal horn of rats receiving either repeated or continuous morphine administration (Table 1). Furthermore, most apoptotic cells were identified as neuronal cells (Fig. 3B), because both apoptosis (TUNEL) and neuronal (NeuN) markers were colocalized in the same cells (Fig. 2G–I). Because the total number of apoptotic cells exceeded that of neuronal apoptotic cells (Fig. 3B), it is likely that some of these apoptotic cells were glial cells (Fig. 2G–I). Thus, apoptosis was induced in the spinal cord dorsal horn of rats made tolerant to morphine after either repeated bolus or continuous intrathecal administration.

Expression of the GABA-synthesizing enzyme GAD in apoptotic neuronal cells

Spinal sections from rats receiving either repeated 20 µg morphine boluses or 20 nmol·µl⁻¹·hr⁻¹ morphine infusion for 7 d were costained with TUNEL and GAD67. Co-localization of both TUNEL and GAD67 immunostaining was clearly observed within the superficial spinal cord dorsal horn lamina (Fig. 2J–L). Consistent with that observed with morphine tolerance (Fig. 1) and associated neuronal apoptosis (Fig. 3A), the magnitude of increase in nociceptive sensitivity was also dose-dependent. That is, a significantly lower baseline foot withdrawal latency was observed in rats treated with a high dose (20 µg or 20 nmol·µl⁻¹·hr⁻¹) than a low dose (10 µg or 10 nmol·µl⁻¹·hr⁻¹) of morphine (Fig. 4A) (p < 0.05). These results indicate that the induction of neuronal apoptosis in morphine-tolerant rats was accompanied by an increase in the sensitivity to noxious heat stimulation, a finding consistent with that demonstrated by previous studies (Mao et al. 1995a; Ossipov et al., 1995; Vanderah et al., 2000).

Increased nociceptive heat sensitivity in rats showing neuronal apoptosis

The baseline foot withdrawal latency was compared between day 0 (baseline) and day 8 in each group. There was no significant difference in the foot-withdrawal latency between days 0 and 8 in the saline-treated rats (Fig. 4A) (p > 0.05). In contrast, the baseline foot withdrawal latency was reduced on day 8, compared with that on day 0 (Fig. 4A) (p < 0.01) in rats receiving either repeated boluses or continuous infusion with morphine for 7 d. Similar to that observed with morphine tolerance (Fig. 1) and associated neuronal apoptosis (Fig. 3A), a magnitude of increase in nociceptive sensitivity was also dose-dependent. That is, a significantly lower baseline foot withdrawal latency was observed in rats treated with a high dose (20 µg or 20 nmol·µl⁻¹·hr⁻¹) than a low dose (10 µg or 10 nmol·µl⁻¹·hr⁻¹) of morphine (Fig. 4A) (p < 0.05). These results indicate that the induction of neuronal apoptosis in morphine-tolerant rats was accompanied by an increase in the sensitivity to noxious heat stimulation, a finding consistent with that demonstrated by previous studies (Mao et al. 1995a; Ossipov et al., 1995; Vanderah et al., 2000).

Contribution of the spinal GT and NMDAR to the induction of neuronal apoptosis

Intrathecal coadministration (twice daily) of morphine (10 µg) and the GT inhibitor PDC (20 µg) for 7 d further increased the number of apoptotic cells within the superficial spinal cord dorsal horn compared with that of the morphine-alone (10 µg) group (Figs. 2A–C, 5A) (p < 0.01). Conversely, apoptotic cells were reduced in rats receiving combined morphine (10 µg) and riluzole (20 µg, a positive regulator of GT activity) for 7 d compared with that of the morphine-alone group (Fig. 5A) (p < 0.05). Neither PDC nor riluzole alone at the current dose induced apoptotic changes (Fig. 5A). Furthermore, riluzole and PDC at its current dose also reduced and enhanced, respectively, the development of morphine tolerance and changes in nociceptive sensitivity in the behavioral tests (Figs. 1B, 4B). Thus, regulation of the spinal GT activity contributes to the induction of apoptosis associated with the development of morphine tolerance and the increase in nociceptive heat sensitivity.

Consistent with the role of spinal GT activity, apoptosis was
clearly blocked in rats receiving coadministration of morphine (20 nmol·μl⁻¹·hr⁻¹) and MK-801 (1 nmol·μl⁻¹·hr⁻¹), a non-competitive NMDAR antagonist) via an intrathecal osmotic pump for 7 d compared with the corresponding morphine-alone group (Fig. 5B) (p < 0.01). The combined administration with morphine and MK-801 also effectively prevented the development of morphine tolerance (Fig. 1B) as well as the increase in nociceptive heat sensitivity (Fig. 4B) when tested on day 8. Neither apoptosis nor changes in morphine antinociception were observed on day 8 in rats infused with MK-801 (1 nmol·μl⁻¹·hr⁻¹, intrathecal) alone for 7 d, indicating that MK-801 specifically blocked the process of morphine tolerance and neuronal apoptosis.

Changes in the spinal caspase-3, Bax, and Bcl-2 protein content in morphine-tolerant rats

Intrathecal administration (twice daily) of 20 μg of morphine for 7 d induced an upregulation of Bax and caspase-3 but a down-regulation of Bcl-2 in the spinal cord dorsal horn, as shown in corresponding Western blots (Fig. 6). Consistently, there was an increase in cell bodies positively stained with cleaved caspase-3 in the superficial dorsal horn of rats treated with 20 nmol·μl⁻¹·hr⁻¹ morphine but not saline for 7 d (Figs. 7A,B, 8A). Such an increase in caspase-3-positive cells was blocked by the coadministration of morphine (20 nmol·μl⁻¹·hr⁻¹) with MK-801 (1 nmol·μl⁻¹·hr⁻¹) for 7 d (Fig. 8A), suggesting that NMDARs play an important role in the caspase-3 increase in morphine-tolerant rats. Importantly, caspase-3 or Bax was colocalized with the TUNEL staining in the spinal cord dorsal horn (Fig. 7C–H), indicating a morphological correlation at the cellular level between caspase-3 or Bax changes and neuronal apoptosis.

**Figure 2.** Induction of neuronal apoptosis after prolonged morphine treatment. A–C, Micrographs from the superficial spinal cord dorsal horn illustrate apoptotic cells in rats receiving repeated intrathecal saline (A), 10 μg morphine boluses (B), and the combination of 10 μg of morphine and 20 μg of PDC (C) for 7 d. D–F, The TUNEL (red) staining co-localizes with condensed and fragmented nuclei, as shown by the Hoechst staining (blue) and the merged image in F, indicating that the TUNEL staining specifically detected in vivo DNA fragmentation (arrows). Note that all TUNEL-positive cells were colocalized with NeuN, indicating the presence of apoptotic glial cells. J–L, The TUNEL (red) staining was colocalized with the NeuN staining (green) as shown in L (merged), indicating that the costained apoptotic cells were neurons in the dorsal horn. Note that some TUNEL-positive cells were not colocalized with NeuN, indicating the presence of apoptotic glial cells. J–L, The TUNEL (red) staining was colocalized with the GAD67 staining (green) as shown in L (merged), indicating that the costained apoptotic cells contain the GABA-synthesizing enzyme and are likely to be GABAergic neurons. Images from D–L were taken from rats receiving intrathecal 20 μg morphine boluses or 20 nmol·μl⁻¹·hr⁻¹ morphine infusion for 7 d. Scale bars: A–C, 30 μm; D–L, 15 μm; D′–F′, 5 μm.
from rats receiving 20 \mu g H9262 infusion. **partially prevented in rats receiving the coadministration of morphine and the increase in nociceptive sensitivity were changes. Furthermore, both tolerance to the antinociceptive effects of morphine and the increase in nociceptive sensitivity were

morphine-alone (20 \mu g) group (Fig. 8B) (p < 0.01). Neither Z-VAD-FMK nor AC-DEVD-CHO alone induced apoptotic changes. Furthermore, both tolerance to the antinociceptive effects of morphine and the increase in nociceptive sensitivity were partially prevented in rats receiving the coadministration of mor-

phine and Z-VAD-FMK or AC-DEVD-CHO (Fig. 8C,D), whereas Z-VAD-FMK or AC-DEVD-CHO (5 \mu g, intrathecal) alone for 7 d did not change baseline latencies and the response to the antinociceptive effects of morphine. These results indicate

that caspases, possibly caspase-3, contribute to the induction of neuronal apoptosis that is in part responsible for the development of morphine tolerance and the associated increase in nociceptive sensitivity.

**DISCUSSION**

The CNS effects of opioids are overwhelmingly inhibitory, and tolerance to opioid analgesia develops after its prolonged administration. Our findings indicate that prolonged exposure to morphine, but not an acute morphine treatment, also induces apoptotic cell death in spinal cord dorsal horn regions critically involved in opioid analgesia, which contributes, at least in part, to the behavioral manifestation of morphine tolerance. A large number of these apoptotic cells are likely to be GABAergic neurons. As such, there is an associated increase in nociceptive heat sensitivity in rats showing neuronal apoptosis. Mechanistically, the spinal glutamatergic activity and the NMDAR play an important role in morphine-induced neuronal apoptosis and the proapoptotic pathway (Bax and possibly caspase-3) is likely to be an intracellular mediator for the induction of neuronal apoptosis in association with the development of morphine tolerance. These results suggest that prolonged exposure to an opioid such as morphine could lead to two seemingly unrelated consequences, pharmacological tolerance and neuronal excitotoxicity in the form of apoptotic cell death.

**Possible mechanisms of morphine-induced neuronal apoptosis**

The present data demonstrate that both morphine tolerance and the associated neuronal apoptosis share a common cellular mechanism at least in part mediated by the NMDAR, because MK-801 blocked both tolerance and apoptosis. This is consistent with the previous observations indicating that (1) NMDA and μ-opioid receptors coexist in single neurons within CNS regions, including the spinal cord (Gracy et al., 1997; Keniston et al., 1998; Commons et al., 1999; Wang et al., 1999); and (2) activation of NMDARs can be facilitated via PKC in neurons treated with an exogenous μ-opioid agonist such as morphine (Chen and Huang, 1991). In addition, our data indicate that the spinal GT activity plays a regulatory role in the cellular mechanisms of morphine-induced neuronal apoptosis. This finding is in agreement with the
data showing reduced GT expression after exposure to opioids in both cortical cell cultures (Thorlin et al., 1998) and brain regions (Ozawa et al., 2001), and such a reduction in GT expression could modulate the development of morphine tolerance (Nakagawa et al., 1994, 1995). The findings from this and previous studies suggest that pro-longed exposure to a μ-opioid such as morphine can lead to two cellular processes within the same neuron (Chen and Huang, 1991; Mao et al. 1995), with the involvement of a neural circuit (Zeitz et al., 2002), or both. These two processes include enhanced NMDAR excitability (NMDAR priming) and increased synaptic glutamate availability in the spinal cord dorsal horn (Fig. 9). As described previously (Mao et al., 1994, 1995b; Mayer et al., 1999), the enhanced NMDAR excitability in response to an opioid may be mediated via activation of PKC (Chen and Huang, 1991; Mao et al. 1995). PKC activation would facilitate, directly or indirectly, the removal of the Mg$^{2+}$ blockade from the NMDAR–Ca$^{2+}$ channel site (Chen and Huang, 1992; Woolf and Salter, 2000), regulate NMDAR trafficking and gating (Lan et al., 2001), or both, thereby increasing the probability of NMDAR activation. The exact PKC isofrm contributing to this process remains uncertain, although PKCy has been suggested to be at least partially involved (Mao et al. 1995; Narita et al., 2001; Zeitz et al., 2002). On the other hand, changes in the spinal GT activity after opioid administration may increase the availability of synaptic glutamate as discussed above. Conceivably, enhanced NMDAR excitability coupled with increased synaptic glutamate availability makes the activation of regional NMDARs possible even in the presence of an overwhelmingly inhibitory opioid effect (Mao et al., 1994, 1995b).

Activation of NMDARs would, in turn, initiate intracellular pathways of apoptotic cell death. Indeed, it has been suggested that multiple intracellular mechanisms may be involved in NMDAR-mediated apoptotic changes. In particular, there may be changes in intracellular proapoptotic elements such as Bax and caspase-3 and antiapoptotic elements such as Bcl-2 in response to NMDAR activation (Du et al., 1997; Tenneti et al., 1998; Allen et al., 1999; Springer et al., 1999; Kwong and Lam, 2000; Nath et al., 2000; Puka-Sundvall et al., 2000; Qin et al., 2000; Tenneti and Lipton, 2000; Bachis et al., 2001; Chan et al., 2001). Recently, chronic morphine treatment has been shown to induce upregulation of the proapoptotic Fas receptor and downregulation of Bcl-2 in the rat brain (Boronat et al., 2001). In the present study, prolonged morphine administration induced upregulation of Bax and caspase-3 and downregulation of Bcl-2. Importantly, the upregulation of caspase-3 and Bax was inhibited when morphine was coadministered with the noncompetitive NMDAR antagonist MK-801, supporting a link between NMDAR activation and intracellular changes of caspase-3 and Bax in response to a prolonged morphine administration. Moreover, similar to the prevention by MK-801 of morphine-induced neuronal apoptosis, inhibition of the spinal caspase-like activity also blocked the induction of morphine-induced neuronal apoptosis. Together, our findings suggest an opioid-induced neurotoxic mechanism that is regulated by the spinal glutamatemic activity and NMDARs as well as the caspase-mediated intracellular apoptotic pathway (Fig. 9).

**Functional relation to opioid tolerance and the associated abnormal pain sensitivity**

Opioids are known to induce *in vitro* apoptosis in multiple cell lines, including neuronal cells (Maneckjee and Minna, 1994; Heusch and Maneckjee, 1999; Singhal et al., 1999; Diao et al., 1998; Mennerick et al., 1999; Jabaund et al., 2000; Vorwerke et al., 2000), although a process that might change glutamate availability at the synaptic level may not necessarily increase the gross regional glutamate content (Jhamandas et al., 1996).

The findings from this and previous studies suggest that prolonged exposure to a μ-opioid such as morphine can lead to two cellular processes within the same neuron (Chen and Huang, 1991; Mao et al. 1995c), with the involvement of a neural circuit (Zeitz et al., 2002), or both. These two processes include enhanced NMDAR excitability (NMDAR priming) and increased synaptic glutamate availability in the spinal cord dorsal horn (Fig. 9). As described previously (Mao et al., 1994, 1995b; Mayer et al., 1999), the enhanced NMDAR excitability in response to an opioid may be mediated via activation of PKC (Chen and Huang, 1991; Mao et al. 1995c). PKC activation would facilitate, directly or indirectly, the removal of the Mg$^{2+}$ blockade from the NMDAR–Ca$^{2+}$ channel site (Chen and Huang, 1992; Woolf and Salter, 2000), regulate NMDAR trafficking and gating (Lan et al., 2001), or both, thereby increasing the probability of NMDAR activation. The exact PKC isofrm contributing to this process remains uncertain, although PKCy has been suggested to be at least partially involved (Mao et al. 1995c; Narita et al., 2001; Zeitz et al., 2002). On the other hand, changes in the spinal GT activity after opioid administration may increase the availability of synaptic glutamate as discussed above. Conceivably, enhanced NMDAR excitability coupled with increased synaptic glutamate availability makes the activation of regional NMDARs possible even in the presence of an overwhelmingly inhibitory opioid effect (Mao et al., 1994, 1995b).

Activation of NMDARs would, in turn, initiate intracellular pathways of apoptotic cell death. Indeed, it has been suggested that multiple intracellular mechanisms may be involved in NMDAR-mediated apoptotic changes. In particular, there may be changes in intracellular proapoptotic elements such as Bax and caspase-3 and antiapoptotic elements such as Bcl-2 in response to NMDAR activation (Du et al., 1997; Tenneti et al., 1998; Allen et al., 1999; Springer et al., 1999; Kwong and Lam, 2000; Nath et al., 2000; Puka-Sundvall et al., 2000; Qin et al., 2000; Tenneti and Lipton, 2000; Bachis et al., 2001; Chan et al., 2001). Recently, chronic morphine treatment has been shown to induce upregulation of the proapoptotic Fas receptor and downregulation of Bcl-2 in the rat brain (Boronat et al., 2001). In the present study, prolonged morphine administration induced upregulation of Bax and caspase-3 and downregulation of Bcl-2. Importantly, the upregulation of caspase-3 and Bax was inhibited when morphine was coadministered with the noncompetitive NMDAR antagonist MK-801, supporting a link between NMDAR activation and intracellular changes of caspase-3 and Bax in response to a prolonged morphine administration. Moreover, similar to the prevention by MK-801 of morphine-induced neuronal apoptosis, inhibition of the spinal caspase-like activity also blocked the induction of morphine-induced neuronal apoptosis. Together, our findings suggest an opioid-induced neurotoxic mechanism that is regulated by the spinal glutamatemic activity and NMDARs as well as the caspase-mediated intracellular apoptotic pathway (Fig. 9).

**Figure 7.** Colocalization of caspase-3 or Bax with the TUNEL staining. A, B. The increase in caspase-3 staining (B) was primarily shown in the superficial dorsal horn of rats receiving a 7 d intrathecal administration (twice daily) of 20 μg of morphine compared with the saline control (A). C–E. The caspase-3 (green, cytosol) staining was colocalized with the TUNEL staining (red, nuclear) as shown in E (merged). F–H. The Bax (green, cytosol) staining also was colocalized with the TUNEL staining (red) as shown in H (merged). In both cases, the photomicrographs were selected from the same group of rats treated with 20 μg of morphine twice daily for 7 d. Scale bars: A, B, 50 μm; C–H, 10 μm.
This opioid-induced apoptosis is considered beneficial for fighting malignant tumor cells. In this experimental paradigm, however, in vivo apoptosis occurred in the spinal cord dorsal horn regions critically involved in opioid analgesia in response to clinically relevant morphine analgesic doses given through a common administration route. Because a large portion of apoptotic cells are likely to be GABAergic neurons within the superficial spinal cord dorsal horn, this morphine-induced neuronal excitotoxic process could lead to changes in spinal neural circuits involved in pain and pain modulation, thereby enhancing pain sensitivity by means of spinal disinhibition.

Indeed, signs of abnormal pain such as hyperalgesia have been observed both in animals exposed to opioids such as morphine and heroin (Mao et al., 1994; Ossipov et al., 1995; Wegert et al., 1997; Vanderah et al., 2000; Celerier et al., 2001) and in human subjects undergoing acute or chronic opioid therapy (Sjogren et al., 1993; Devulder, 1997). This is further supported by the present data showing increased nociceptive heat sensitivity in rats with neuronal apoptosis, which was potentiated by the GT inhibitor PDC. However, both apoptosis and increased nociceptive heat sensitivity were prevented by the noncompetitive NMDAR antagonist MK-801. Of significance to note is that the present data indicate a functional link between morphine-induced apoptosis, morphine tolerance, and tolerance-related abnormal nociceptive sensitivity, because inhibition of morphine-induced apoptosis by the relatively selective caspase-3 inhibitor AC-DEVD-CHO partially prevented morphine tolerance and the associated increase in nociceptive heat sensitivity. An interesting distinction between the effects of MK-801 and AC-DEVD-CHO is that both tolerance and increased nociceptive sensitivity were effectively prevented by MK-801 but incompletely prevented by AC-DEVD-CHO, suggesting that morphine-induced neuronal apoptosis may contribute to the cellular mechanisms of morphine tolerance and the associated increase in nociceptive sensitivity.

Clinical implications
The present findings suggest important implications in chronic opioid therapy. First, if neuronal apoptosis is a part of the neural mechanisms of opioid tolerance, tolerance to opioids would be less likely to fully recover and more likely to be exacerbated in the subsequent opioid therapy in the clinical setting. Second, opioid-induced apoptosis would be of particular concern in cancer pain and chronic nonmalignant pain treatment that often requires...
Another clinical implication of the present findings is related to the field of substance abuse. Neurobehavioral changes indicative of drug addiction can be seen after exposure to a substance of abuse such as cocaine, alcohol, or heroin. A common feature of such neurobehavioral changes is the difficulty of rehabilitation, with a high tendency of relapse. Critically, activation of NMDARs has been extensively implicated in the neural mechanisms of such neurobehavioral changes (De Montis et al., 1992; Cebere et al., 1999; Churchill et al., 1999; Cornish et al., 1999; Huber et al., 2001), and neuronal apoptosis has indeed been observed in the prenatal and early postnatal stages of animals exposed to a substance of abuse (Nassogne et al., 1997; He et al., 1999). Therefore, a corollary of our findings showing opioid-induced apoptosis in adult rats is that persistent CNS changes in the form of apoptosis may be triggered by a substance of abuse and may contribute to clinical features of substance abuse.

In summary, we found that a subgroup of neurons, as well as glial cells, primarily located in the superficial laminae of the spinal cord dorsal horn and likely to be inhibitory GABAergic neurons, undergo the NMDAR- and caspase-mediated apoptotic process in association with the development of morphine tolerance. These findings may have significant clinical implications in relation to chronic opioid therapy and substance abuse.

Figure 9. Possible mechanisms of opioid-induced neuronal apoptosis. The data from both previous and present studies suggest that NMDAR activation may be initiated after prolonged exposure to a μ-opioid agonist such as morphine by means of increased NMDA excitability and regional glutamate availability. NMDAR activation would enhance intracellular positive apoptosis regulators such as Bax and caspases and decrease negative apoptosis regulators such as Bcl-2. The resultant apoptosis contributes, at least in part, to the neural mechanisms of opioid tolerance and the associated increase in abnormal pain sensitivity. Dashed lines indicate the involvement of additional intermittent steps.

prolonged use of opioids. A loss of opioid analgesic efficacy attributable to tolerance in combination with enhanced pain sensitivity secondary to neurotoxicity would compromise the outcome of chronic opioid therapy and more importantly would lead to persistent changes in the neural circuits involved in pain and pain modulation. This may be reflected as repeated dose escalation during opioid therapy regardless of disease progression and an intractable chronic pain state refractory to opioid treatment, because opioid therapy itself may be the driving force for such a condition. Third, such a consequence could be further exacerbated in neuropathic pain treatment with opioids, because neuropathic pain itself may be associated with the CNS neurotoxic changes (Mao et al. 1992b, 1997; Kawamura et al., 1997; Whiteside and Munglani, 2001). As indicated by the present data, however, blockade of NMDARs, modulation of the spinal GT activity, inhibition of intracellular proapoptotic elements, or a combination of the three during opioid therapy may help prevent the development of opioid-induced neurotoxic changes.
