

# Generation of Reactive Oxygen Species in the Reaction Catalyzed by $\alpha$ -Ketoglutarate Dehydrogenase

Laszlo Tretter and Vera Adam-Vizi

Department of Medical Biochemistry, Semmelweis University, and Neurochemistry Group, Hungarian Academy of Sciences, Budapest H-1444, Hungary

$\alpha$ -Ketoglutarate dehydrogenase ( $\alpha$ -KGDH), a key enzyme in the Krebs' cycle, is a crucial early target of oxidative stress (Tretter and Adam-Vizi, 2000). The present study demonstrates that  $\alpha$ -KGDH is able to generate  $H_2O_2$  and, thus, could also be a source of reactive oxygen species (ROS) in mitochondria. Isolated  $\alpha$ -KGDH with coenzyme A (HS-CoA) and thiamine pyrophosphate started to produce  $H_2O_2$  after addition of  $\alpha$ -ketoglutarate in the absence of nicotinamide adenine dinucleotide-oxidized ( $NAD^+$ ).  $NAD^+$ , which proved to be a powerful inhibitor of  $\alpha$ -KGDH-mediated  $H_2O_2$  formation, switched the  $H_2O_2$  forming mode of the enzyme to the catalytic [nicotinamide adenine dinucleotide-reduced (NADH) forming] mode. In contrast, NADH stimulated  $H_2O_2$  formation by  $\alpha$ -KGDH, and for this, neither  $\alpha$ -ketoglutarate nor HS-CoA were required. When all of the substrates and cofactors of the enzyme were present, the  $NADH/NAD^+$  ratio determined the rate of  $H_2O_2$  production. The higher the  $NADH/NAD^+$  ratio the higher the rate of  $H_2O_2$  production.  $H_2O_2$  production as well as the catalytic function of the enzyme was activated by  $Ca^{2+}$ . In synaptosomes, using  $\alpha$ -ketoglutarate as respiratory substrate, the rate of  $H_2O_2$  production increased by 2.5-fold, and aconitase activity decreased, indicating that  $\alpha$ -KGDH can generate  $H_2O_2$  in *in situ* mitochondria. Given the  $NADH/NAD^+$  ratio as a key regulator of  $H_2O_2$  production by  $\alpha$ -KGDH, it is suggested that production of ROS could be significant not only in the respiratory chain but also in the Krebs' cycle when oxidation of NADH is impaired. Thus  $\alpha$ -KGDH is not only a target of ROS but could significantly contribute to generation of oxidative stress in the mitochondria.

**Key words:** mitochondria; synaptosome;  $\alpha$ -ketoglutarate dehydrogenase; hydrogen peroxide; oxidative stress;  $NADH/NAD$  ratio

## Introduction

Involvement of mitochondria in tissue damage generated by reactive oxygen species (ROS) has been implicated in the pathogenesis of many diseases (Beal, 1996; Halliwell and Gutteridge, 1998). Mitochondria are considered crucial targets of free radical-mediated damage (Kowaltowski and Vercesi, 1999), because both the mitochondrial electron transport chain (Tretter et al., 1987; Bindoli, 1988) and enzymes of the citric acid cycle (Patel et al., 1996; Andersson et al., 1998; Humphries and Szweda, 1998) are vulnerable to oxidative insults. As a result, vital mitochondrial functions, including energy production (Otani et al., 1984; Fiskum, 1985), maintenance of plasma membrane potential (Tretter and Adam-Vizi, 1996), and cellular ionic homeostasis (Chinopoulos et al., 2000), are impaired in the early phase of oxidative stress. Oxidative insults might also induce secondary events leading to apoptosis (Liu et al., 1996).

In contrast, mitochondria are also considered a major site of ROS production (Chance et al., 1979). Operation of the mitochondrial electron transport system leads to formation of superoxide (Loschen et al., 1971; Boveris and Cadenas, 1975), which is

avidly dismutated to  $H_2O_2$  by the superoxide dismutases (Fridovich, 1995). Restriction of electron flow in the respiratory chain resulting from inhibition of complex III (Loschen et al., 1973) or complex I (Votyakova and Reynolds, 2001; Starkov and Fiskum, 2003) favors the formation of superoxide and  $H_2O_2$ . Recently, on synaptosomes, we established that the mitochondrial  $H_2O_2$  generation caused by complex I inhibition could be physiologically more important than that induced by inhibition of complex III and IV *in situ* (Sipos et al., 2003).

We demonstrated previously that  $\alpha$ -ketoglutarate dehydrogenase ( $\alpha$ -KGDH) is sensitive to inhibition by  $H_2O_2$ , and impaired function of this enzyme plays a key role in limiting the generation of nicotinamide adenine dinucleotide-reduced (NADH) in the Krebs' cycle during the early phase of oxidative stress in synaptosomes (Tretter and Adam-Vizi, 2000).  $\alpha$ -KGDH in heart and microglia mitochondria is also sensitive to inhibition by  $H_2O_2$  (Nulton-Persson et al., 2003) and by peroxynitrite (Park et al., 1999), respectively.

$\alpha$ -KGDH is heavily regulated, as reviewed recently (Gibson et al., 2000), adjusting the rate of the Krebs' cycle to metabolic demand. Isolated dihydrolipoyl dehydrogenase, a subunit of  $\alpha$ -KGDH, is able to catalyze NADH oxidation by oxygen with the concomitant formation of  $H_2O_2$  (Huennekens et al., 1955; Gazaryan et al., 2002). Studies on flavoenzymes have demonstrated the possibility of  $H_2O_2$  formation. However, in the case of the dehydrogenases, the reoxidation of reduced enzyme by  $O_2$  was found to be slow (Massey et al., 1969). Very recently, radical species as side products in the 2-oxo acid dehydrogenase reaction

were detected by spin trapping, accompanied by inactivation of the enzyme (Bunik and Sievers, 2002). However, it is not known under what conditions  $\alpha$ -KGDH, a key dehydrogenase in the Krebs' cycle, could generate measurable amounts of ROS during its catalytic function.

The present work demonstrates that isolated  $\alpha$ -KGDH is able to produce ROS, which is regulated by the NADH/nicotinamide adenine dinucleotide-oxidized (NAD<sup>+</sup>) ratio. Thus,  $\alpha$ -KGDH is not only a crucial target of ROS but could significantly contribute to generation of oxidative stress in the mitochondria.

## Materials and Methods

**Preparation of synaptosomes.** Isolated nerve terminals (synaptosomes) were prepared from brain cortex of guinea pigs as detailed previously (Chinopoulos et al., 2000). The pellet obtained after centrifugation at 20,000  $\times$  g for 20 min was suspended in 0.32 M sucrose ( $\sim$ 20 mg/ml of protein) and kept on ice. For additional manipulations, aliquots from this suspension were used. Incubations were performed in standard medium containing the following (in mM): 140 NaCl, 3 KCl, 2 MgCl<sub>2</sub>, 2 CaCl<sub>2</sub>, 10 PIPES, pH 7.38, at 37°C as described below.

**Measurement of H<sub>2</sub>O<sub>2</sub> release from synaptosomes.** The assay is based on the detection of H<sub>2</sub>O<sub>2</sub> in the medium using the Amplex Red fluorescent dye (Mohanty et al., 1997). In the presence of horseradish peroxidase, the Amplex Red reagent reacts with H<sub>2</sub>O<sub>2</sub> with a 1:1 stoichiometry producing highly fluorescent resorufin. Synaptosomes (0.5 mg/ml) were incubated for 1 hr in the standard medium containing no substrate, or 10 mM glucose, or 5 mM  $\alpha$ -ketoglutarate ( $\alpha$ -KG) (see Fig. 1 for details) and then horseradish peroxidase (1 U per 2 ml) and Amplex Red reagent (1  $\mu$ M) were added. H<sub>2</sub>O<sub>2</sub> released from synaptosomes was detected at 37°C using a Photon Technology International (PTI; Lawrenceville, NJ) Deltascan fluorescence spectrophotometer; the excitation wavelength was 550 nm, and the fluorescence emission was detected at 585 nm. A calibration curve was generated with known amounts of H<sub>2</sub>O<sub>2</sub> at the end of each experiment.

**Assay for aconitase activity.** Aconitase was assayed as described by Hausladen and Fridovich (1996) and detailed previously (Tretter and Adam-Vizi, 2000). Briefly, synaptosomes (1 mg/ml protein) were incubated in the absence or presence of  $\alpha$ -ketoglutarate (5 mM) for 1 hr at 37°C and then aliquots of synaptosomes (0.4 mg of protein) were transferred to an assay medium containing the following (in mM): 50 Tris-HCl, 0.6 MnCl<sub>2</sub>, 30 sodium citrate, 0.2% Triton X-100, 2 U/ml isocitrate dehydrogenase (NADP<sup>+</sup> dependent), and 1 U/ml catalase at 37°C, pH 7.4. The reaction was initiated by the addition of 0.2 mM NADP<sup>+</sup>. The fluorescence intensity was determined with a PTI Deltascan fluorescence spectrophotometer using 344 nm excitation and 460 nm emission wavelength, respectively. Changes in NADPH concentration were quantified using a calibration curve with known amounts of NADPH.

**Parallel assay of  $\alpha$ -KGDH activity and H<sub>2</sub>O<sub>2</sub> generation by  $\alpha$ -KGDH.** Experiments on isolated  $\alpha$ -KGDH were done with the commercially available enzyme isolated from porcine hearts (lots 58H7440 and 32K7445; Sigma, St. Louis, MO). The Sigma preparation is a solution of purified  $\alpha$ -KGDH in 50% glycerol containing 10 mg/ml of bovine serum albumin, 30% sucrose, 2.5 mM EGTA, 2.5 mM 2-mercaptoethanol, 0.5% Triton X-100, 0.0055% sodium azide, and 25 mM potassium phosphate, pH 6.8. According to the specifications of the manufacturer, the enzyme activity was 9.4 U/ml for lot 58H7440 and 6 U/ml for lot 32K7445.

$\alpha$ -Ketoglutarate dehydrogenase was assayed similarly as described previously (Lai and Cooper, 1986). Aliquots of  $\alpha$ -ketoglutarate dehydrogenase (2  $\mu$ l from lot 58H7440 or 3  $\mu$ l from lot 32K7445, giving similar results) were added to a medium containing 50 mM potassium phosphate, 0.2 mM thiamine pyrophosphate, 0.5 mM MgCl<sub>2</sub>, 0.4 mM ADP, 1 mM NAD<sup>+</sup> where indicated, and 0.1 mM EGTA, pH 7.4. The reaction was initiated by the addition of 0.12 mM coenzyme A (HS-CoA) and 1 mM  $\alpha$ -ketoglutarate. NADH and Amplex fluorescence (detailed above) was measured simultaneously using 340 and 550 nm excitation and 466 and 585 nm emission wavelengths, respectively. The assays were performed at 37°C. The two lots of Sigma  $\alpha$ -KGDH used throughout the experiments gave essentially similar results.

For measurements on the Ca<sup>2+</sup> dependency of  $\alpha$ -KGDH, different Ca<sup>2+</sup> concentrations in the medium were established. For this, aliquots from a calcium calibration buffer kit were added to the ADP and Mg<sup>2+</sup> free assay medium, and free ionized [Ca<sup>2+</sup>] was measured by unesterified Fura-2 and Fura-6F (1  $\mu$ M) at 340 and 380 nm excitation and 510 nm emission wavelength, respectively. Free calcium concentrations were calculated from the Grynkiewicz equation (Grynkiewicz et al., 1985).

**Statistics.** Results are expressed either as original traces or as mean  $\pm$  SEM values. Statistical differences were calculated using one-way ANOVA. Differences were considered significant at a level of  $p < 0.05$ .

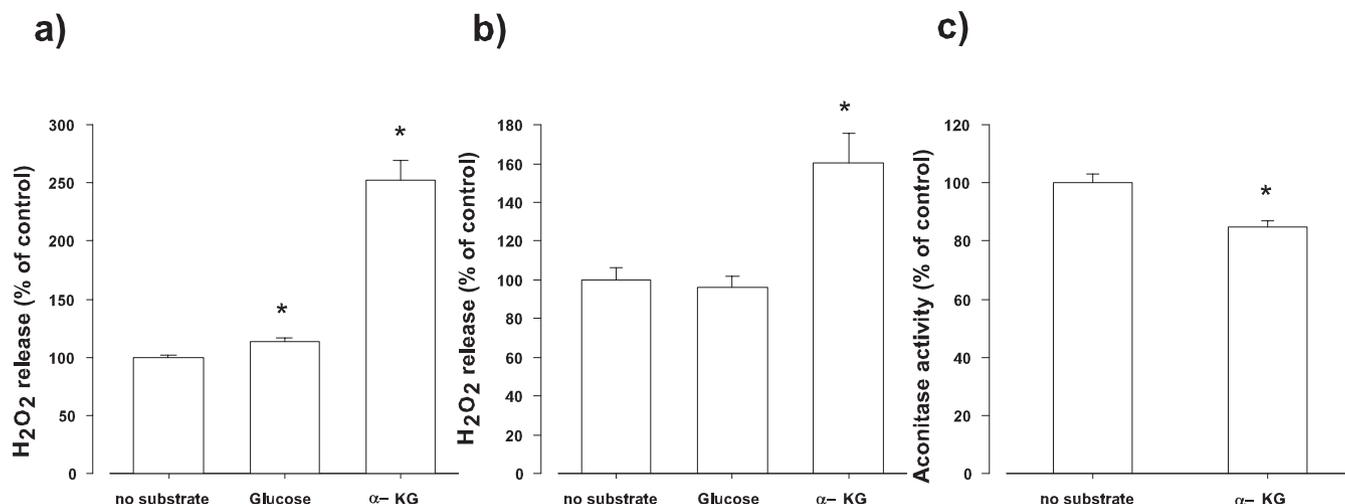

**Materials.** Standard laboratory chemicals were obtained from Sigma. Special peroxide-free and carbonyl-free Triton X-100 (Sigma) was used throughout the experiments for disrupting synaptosomal membranes. The Amplex Red reagent, Fura-6F, and the calcium calibration buffer kit were from Molecular Probes (Eugene, OR).

## Results

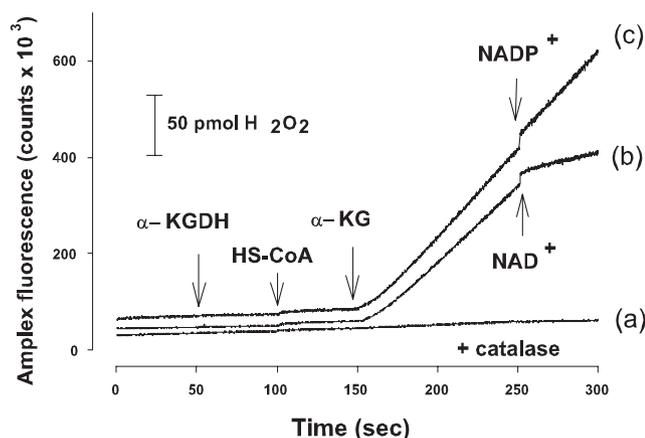

### Enhanced H<sub>2</sub>O<sub>2</sub> generation in synaptosomes in the presence of $\alpha$ -ketoglutarate

We reported previously that a significant amount of H<sub>2</sub>O<sub>2</sub> is produced in synaptosomes incubated in normal glucose-containing medium under resting, nonstimulated conditions (Sipos et al., 2003). Here, we investigated whether H<sub>2</sub>O<sub>2</sub> production is different when  $\alpha$ -KG, an alternative substrate, maintains the metabolism in intact synaptosomes. It has been established that  $\alpha$ -KG is taken up by synaptosomes with high- and low-affinity carriers (Shank and Campbell, 1984; Willoughby et al., 1989), and by directly fueling a key regulatory enzyme,  $\alpha$ -KGDH in the Krebs' cycle supports respiration in the *in situ* mitochondria (Willoughby et al., 1989). We also controlled that under conditions used for Figure 1*a* (see below), addition of  $\alpha$ -KG (5 mM) to the medium indeed resulted in an immediate increase in the oxygen consumption (data not shown), reinforcing the role of  $\alpha$ -KG as a substrate for *in situ* mitochondria. With Amplex Red, H<sub>2</sub>O<sub>2</sub> released from synaptosomes was measured, the fluorescence being proportional to the generation of H<sub>2</sub>O<sub>2</sub>. However, a part of the oxidant was eliminated intracellularly by glutathione peroxidase and catalase (Chen et al., 2003) and remains undetected.

H<sub>2</sub>O<sub>2</sub> generation was compared in glucose and  $\alpha$ -KG-containing medium immediately after addition of the substrates (Fig. 1*a*) or after incubation for 1 hr (Fig. 1*b*). The rate of H<sub>2</sub>O<sub>2</sub> release from synaptosomes incubated for 1 hr in the absence of added substrates was 12.7  $\pm$  0.17 pmol/min/mg protein. After addition of glucose (10 mM) to the medium, H<sub>2</sub>O<sub>2</sub> release increased by 13.6  $\pm$  3.1% (Fig. 1*a*). When instead of glucose,  $\alpha$ -KG (5 mM) was given to synaptosomes, the increase in H<sub>2</sub>O<sub>2</sub> release was 2.5-fold (from 12.7  $\pm$  0.17 to 32.0  $\pm$  2.2 pmol/min/mg) (Fig. 1*a*). A remarkable increase in H<sub>2</sub>O<sub>2</sub> generation by  $\alpha$ -KG was also measured after incubation for 1 hr in the presence of this substrate (Fig. 1*b*). When glucose was present in the medium for 1 hr, no significant difference in the H<sub>2</sub>O<sub>2</sub> release was found (Fig. 1*b*). The effect of  $\alpha$ -KG on the H<sub>2</sub>O<sub>2</sub> generation was confirmed by measuring the activity of endogenous aconitase. This enzyme is highly sensitive to different ROS, and decrease in the activity of aconitase is a marker of an enhanced ROS production (Patel et al., 1996; Liang et al., 2000; Sipos et al., 2003). It is demonstrated in Figure 1*c* that the activity of the endogenous aconitase was significantly decreased in synaptosomes (16  $\pm$  2.4%) incubated in the presence of  $\alpha$ -KG for 1 hr.  $\alpha$ -KG had no direct effect on aconitase, as controlled in a separate assay (data not shown). These results indicate that H<sub>2</sub>O<sub>2</sub> production is elevated in intact synaptosomes in the presence of  $\alpha$ -KG. This somewhat unexpected result raised the possibility that  $\alpha$ -KG could directly con-

**Figure 1.**  $H_2O_2$  release from synaptosomes as measured by a direct assay with Amplex Red (*a*, *b*) or by the activity of endogenous aconitase (*c*). *a*, Synaptosomes (0.5 mg of protein/ml) were incubated for 1 hr in glucose-free medium, and then Amplex Red and HRP were added. The rate of  $H_2O_2$  release was measured after addition of glucose (10 mM) or  $\alpha$ -KG (5 mM). The results are expressed as percentage of the rate of  $H_2O_2$  release from synaptosomes observed in the absence of added substrates ( $12.7 \pm 0.17$  pmol/min/mg synaptosomal protein;  $\pm$  SEM;  $n = 4$ ). *b*, Synaptosomes were incubated for 1 hr in glucose-free medium (control) or in the presence of glucose (10 mM) or  $\alpha$ -KG (5 mM), and then the rate of  $H_2O_2$  release was measured. Bars indicate the rate of  $H_2O_2$  release as percentage of control ( $12.1 \pm 0.77$  pmol/min/mg synaptosomal protein;  $\pm$  SEM;  $n = 4$ ). *c*, Synaptosomes were incubated in the standard medium for 1 hr in the absence (control) or presence of  $\alpha$ -KG (5 mM), and then the activity of aconitase was measured as described in Materials and Methods. Aconitase activity is expressed as percentage of control ( $6.3 \pm 0.19$  nmol/min/mg synaptosomal protein;  $\pm$  SEM;  $n = 5$ ). Asterisk indicates significant difference from the corresponding controls.

**Figure 2.**  $H_2O_2$  production by isolated  $\alpha$ -KGDH.  $H_2O_2$  formation was measured with Amplex Red as detailed in Materials and Methods. For *a–c*,  $\alpha$ -KGDH, HS-CoA (0.12 mM), and  $\alpha$ -KG (1 mM) were added as indicated. For *a*, catalase was given before  $\alpha$ -KGDH.  $NAD^+$  (*b*) or  $NAD^+$  (*c*) (5  $\mu$ M) was given as shown. Traces have been offset for clarity.

tribute to  $H_2O_2$  generation. Three important enzymes could use  $\alpha$ -KG as a substrate: glutamate dehydrogenase, transaminases, and  $\alpha$ -KGDH. We controlled with isolated glutamate dehydrogenase that the enzyme, when  $\alpha$ -KG is the substrate, produces no  $H_2O_2$ . Similarly, no  $H_2O_2$  formation was detected in the reaction catalyzed by isolated glutamate-oxaloacetate transaminase (data not shown). In addition, preincubation of synaptosomes with the transaminase inhibitor D,L-vinylglycine (Lai and Cooper, 1986) was without effect on the  $H_2O_2$  generation observed in the presence of  $\alpha$ -KG (data not shown).

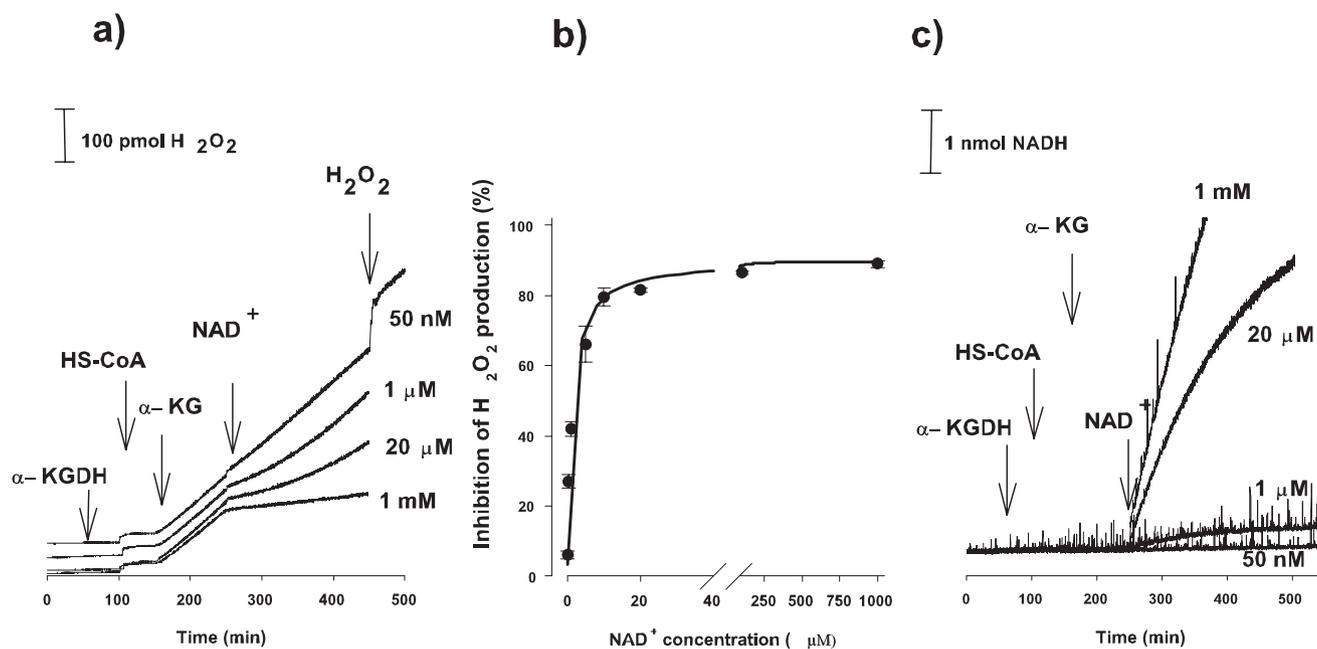

### $H_2O_2$ generation by isolated $\alpha$ -KGDH

To test the possibility that  $H_2O_2$  derives from the  $\alpha$ -KGDH-catalyzed reaction, we measured the rate of  $H_2O_2$  production in a standard assay medium used for measuring the activity of isolated  $\alpha$ -KGDH. In the presence of  $\alpha$ -KGDH and HS-CoA (0.12 mM), addition of  $\alpha$ -KG (1 mM) induced an abrupt increase in the

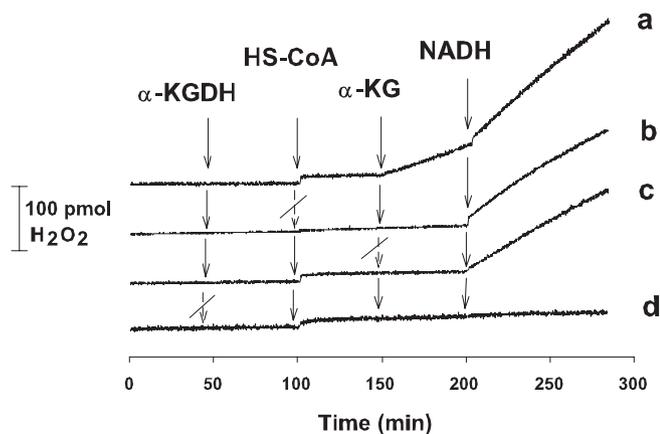

Amplex Red fluorescence (Fig. 2). The fluorescence signal did not increase further when superoxide dismutase was given after the addition of  $\alpha$ -KG (data not shown) but was completely prevented when catalase was also present in the medium (Fig. 2, trace *a*); thus, the fluorescence increase could be attributed to  $H_2O_2$  production. After addition of 5  $\mu$ M  $NAD^+$ ,  $H_2O_2$  production was inhibited, whereas  $NAD^+$  was without effect (Fig. 2, trace *b,c*). These experiments indicate that in the presence of its substrates ( $\alpha$ -KG, HS-CoA), but in the absence of  $NAD^+$ ,  $\alpha$ -KGDH is able to produce ROS. In the standard assay medium, the rate of  $H_2O_2$  generation was  $1.07 \pm 0.07$  pmol/sec ( $n = 16$ ). We could also detect superoxide formation in this reaction as measured with the reduction of the acetylated cytochrome *c* assay (data not shown), which is in agreement with the observation made by Starkov et al. (2004) and Bunik and Sievers (2002). It was not possible to determine whether superoxide was quickly and spontaneously dismutated to  $H_2O_2$ , or whether both superoxide and  $H_2O_2$  were generated in the enzyme reaction. In the present work,  $H_2O_2$  generation was measured to characterize the  $\alpha$ -KGDH-mediated ROS formation.

### $H_2O_2$ production by $\alpha$ -KGDH is inhibited by $NAD^+$

Representative traces showing the effect of  $NAD^+$  (50 nM to 1 mM) on the  $H_2O_2$  production by the isolated  $\alpha$ -KGDH are demonstrated in Figure 3*a*. Proportional with the increase in  $NAD^+$  concentration, the rate of  $H_2O_2$  generation decreased and was almost completely eliminated in the presence of 1 mM  $NAD^+$ . In this experiment, the rate of  $H_2O_2$  formation decreased from 1.07 to 0.15 pmol/sec (86% inhibition) in response to the addition of 1 mM  $NAD^+$ . Inhibition of the rate of  $H_2O_2$  production as a function of  $NAD^+$  concentration is shown in Figure 3*b*. The  $ID_{50}$  ( $NAD^+$  concentration at which the rate of  $H_2O_2$  generation initiated by 1 mM  $\alpha$ -KG is inhibited by 50%) derived from Figure 3 is  $1.58 \pm 0.21$   $\mu$ M. We found that after addition of  $NAD^+$  in 1 or 20  $\mu$ M concentrations, the rate of the diminished  $H_2O_2$  generation was not linear but appeared to slowly recover (Fig. 3*a*) parallel with the conversion of  $NAD^+$  to NADH by  $\alpha$ -KGDH (Fig. 3*c*).

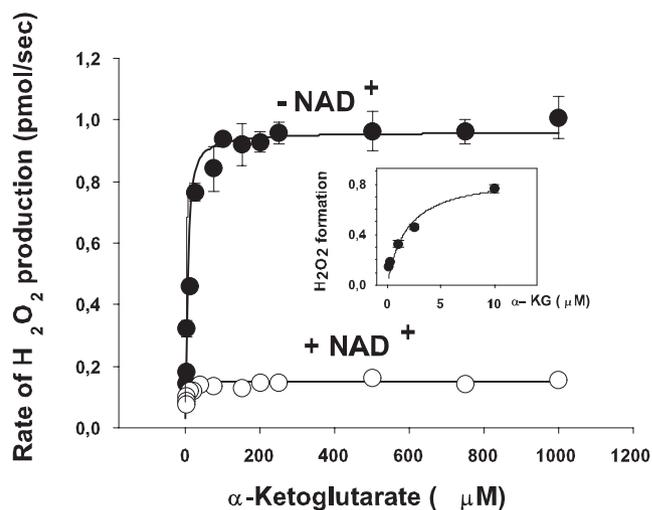

**Figure 3.** Inhibition of H<sub>2</sub>O<sub>2</sub> production (*a, b*) and stimulation of NADH formation (*c*) by isolated  $\alpha$ -KGDH in response to NAD<sup>+</sup>.  $\alpha$ -KGDH, HS-CoA (0.12 mM),  $\alpha$ -KG (1 mM), and NAD<sup>+</sup> in different concentrations (50 nM to 1 mM) were applied as indicated. H<sub>2</sub>O<sub>2</sub> and NADH formations were measured simultaneously in the same samples, as described in Materials and Methods. Traces have been offset for clarity. *b*, Inhibition of H<sub>2</sub>O<sub>2</sub> generation is shown as a function of NAD<sup>+</sup> concentrations. Points represent mean values from three experiments  $\pm$  SEM. Rectangular hyperbola was fitted to the experimental points. H<sub>2</sub>O<sub>2</sub> generation in the absence of NAD<sup>+</sup> was  $1.07 \pm 0.01$  pmol/sec ( $n = 6$ ).

**Figure 4.** Stimulation of  $\alpha$ -KGDH-mediated H<sub>2</sub>O<sub>2</sub> production by NADH.  $\alpha$ -KGDH, HS-CoA (0.12 mM),  $\alpha$ -KG (1 mM), and NADH (1  $\mu$ M) were applied as indicated. H<sub>2</sub>O<sub>2</sub> production was measured as for Figures 2 and 3.

#### Stimulation by NADH of the $\alpha$ -KGDH-mediated H<sub>2</sub>O<sub>2</sub> formation

Next, we investigated the effect of NADH (without NAD<sup>+</sup>) on the H<sub>2</sub>O<sub>2</sub> generation by  $\alpha$ -KGDH. It is demonstrated in Figure 4*a* that 1  $\mu$ M NADH, given 50 sec after addition of  $\alpha$ -KG, further increased the rate of H<sub>2</sub>O<sub>2</sub> formation (in this experiment, from 1.18 to 2.1 pmol/sec). It is also shown in Figure 4 that when HS-CoA or  $\alpha$ -KGDH were not present,  $\alpha$ -KG failed to initiate H<sub>2</sub>O<sub>2</sub> generation (*b, d*). In contrast, NADH was able to induce H<sub>2</sub>O<sub>2</sub> formation in the absence of HS-CoA (*b*) or  $\alpha$ -KG (*c*) or both (data not shown). Only when  $\alpha$ -KGDH was absent was NADH unable to stimulate H<sub>2</sub>O<sub>2</sub> generation (*d*). These results clearly show that for the H<sub>2</sub>O<sub>2</sub> generation initiated by  $\alpha$ -KG, the substrates of  $\alpha$ -KGDH (except for NAD<sup>+</sup>) are essential, whereas only the enzyme is necessary and sufficient for the NADH-induced H<sub>2</sub>O<sub>2</sub> production. This indicates that the mechanism by

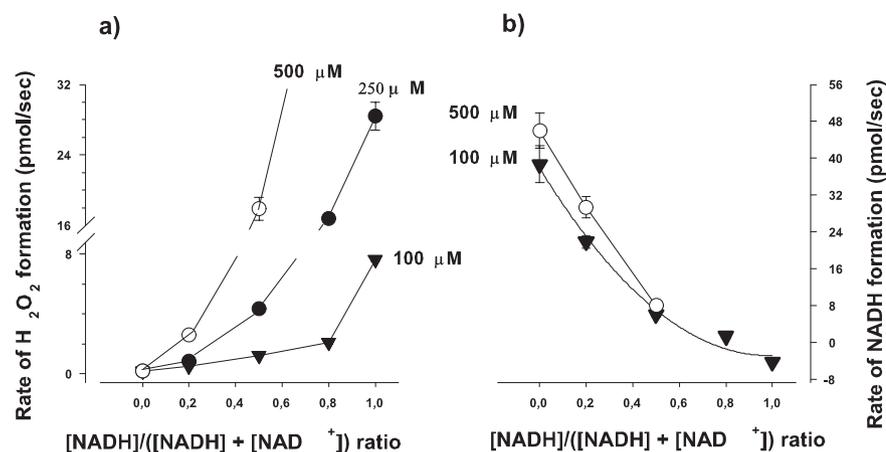

**Figure 5.** H<sub>2</sub>O<sub>2</sub> formation by isolated  $\alpha$ -KGDH as a function of  $\alpha$ -KG. The experimental protocol was as for Figure 2, except that  $\alpha$ -KG was added in different concentrations. The rate of the initial H<sub>2</sub>O<sub>2</sub> formation was measured after addition of  $\alpha$ -KG without (●) or with (○) subsequent application of NAD<sup>+</sup> in 1 mM concentration. H<sub>2</sub>O<sub>2</sub> formation at low concentrations of  $\alpha$ -KG (1–10  $\mu$ M) in the absence of NAD<sup>+</sup> is shown in the inset. Points represent mean  $\pm$  SEM from three experiments. SEM is within the size of symbols unless otherwise indicated.

which  $\alpha$ -KGDH generates H<sub>2</sub>O<sub>2</sub> in response to NADH is different from that initiated by  $\alpha$ -KG in the presence of the substrates and cofactors of the enzyme but in the absence of NAD<sup>+</sup>.

#### H<sub>2</sub>O<sub>2</sub> generation by isolated $\alpha$ -KGDH as a function of $\alpha$ -KG concentration

To further characterize the  $\alpha$ -KGDH-mediated H<sub>2</sub>O<sub>2</sub> production, the rate of H<sub>2</sub>O<sub>2</sub> production was measured as a function of the concentration of  $\alpha$ -KG (Fig. 5). When NAD<sup>+</sup> (1 mM) was present, the rate of H<sub>2</sub>O<sub>2</sub> formation was low; in the presence of 1 mM  $\alpha$ -KG, the rate was  $0.15 \pm 0.02$  pmol/sec. Under identical

**Figure 6.** The effect of NADH/NADH plus NAD<sup>+</sup> ratio on the  $\alpha$ -KGDH-mediated H<sub>2</sub>O<sub>2</sub> and NADH formation. Experiments were performed as described for Figure 3; however, subsequent to  $\alpha$ -KG, NADH plus NAD<sup>+</sup> was added in different ratios shown in the abscissa at final concentrations of 100, 250, or 500  $\mu$ M (*a*) and 100 or 500  $\mu$ M (*b*) as indicated. The rate of H<sub>2</sub>O<sub>2</sub> (*a*) and NADH formation (*b*) were measured after addition of NADH plus NAD<sup>+</sup>. Addition of NADH in this concentration range resulted in a sharp increase in the Amplex signal because of the presence of some H<sub>2</sub>O<sub>2</sub> contamination always present in NADH solutions. Thereafter, the signal became linear, and the slope was taken as a measure of H<sub>2</sub>O<sub>2</sub> generation under the indicated conditions. Catalytic activity of  $\alpha$ -KGDH was followed by the reduction of NAD<sup>+</sup>, measuring absorbance changes at 340 nm with a GBC Scientific Equipment (Dandenong, Australia) UV-visible 920 spectrophotometer, using the extinction coefficient  $E^{340} = 6.22 \text{ mm}^{-1} \cdot \text{cm}^{-1}$ . Points represent mean values from three experiments ( $\pm$  SEM). SEM is within the size of symbols unless otherwise indicated.

conditions, the rate of NADH formation was  $44 \pm 4.1$  pmol/sec ( $n = 3$ ; data not shown). H<sub>2</sub>O<sub>2</sub> formation was found to be concentration dependent in the lower  $\alpha$ -KG concentration range; the  $K_M$  derived from the fitted rectangular hyperbola using the Michaelis equation was  $3.8 \pm 1.1 \mu$ M. In the absence of NAD<sup>+</sup>, as demonstrated in Figures 2 and 3, the rate of H<sub>2</sub>O<sub>2</sub> formation was increased, but the dependence on  $\alpha$ -KG concentrations remained the same (Fig. 5, inset), and the  $\alpha$ -KG  $K_M$  for H<sub>2</sub>O<sub>2</sub> formation in the absence of NAD<sup>+</sup> was not significantly different from that found in the presence of 1 mM NAD<sup>+</sup>. At 1 mM  $\alpha$ -KG concentration, we found a seven times higher rate of H<sub>2</sub>O<sub>2</sub> generation ( $1.05 \pm 0.06$  pmol/sec) in the absence of NAD<sup>+</sup> compared with that measured in the presence of NAD<sup>+</sup> ( $0.15 \pm 0.02$  pmol/sec).

#### H<sub>2</sub>O<sub>2</sub> formation by $\alpha$ -KGDH at different NADH/NAD<sup>+</sup> ratios

Given the opposite effect of NAD<sup>+</sup> and NADH on the  $\alpha$ -KGDH-mediated H<sub>2</sub>O<sub>2</sub> generation, it is important to investigate the dependence of H<sub>2</sub>O<sub>2</sub> formation on the NADH/NAD<sup>+</sup> ratio. Total NADH plus NAD<sup>+</sup> concentrations used in these experiments were 100, 250, or 500  $\mu$ M, and at each concentration, different NADH/NADH plus NAD<sup>+</sup> ratios were set. (At  $>500 \mu$ M NADH plus NAD<sup>+</sup>, when the NADH/NADH plus NAD<sup>+</sup> ratio was  $>0.5$ , H<sub>2</sub>O<sub>2</sub> formation was extremely rapid, making the calculation of the rate of H<sub>2</sub>O<sub>2</sub> formation unreliable. Therefore, higher than 500  $\mu$ M NADH plus NAD<sup>+</sup> concentration was not used in these experiments). The rates of H<sub>2</sub>O<sub>2</sub> and NADH formation after addition of NADH plus NAD<sup>+</sup> were measured simultaneously (Fig. 6*a,b*). As a general tendency, it is apparent from Figure 6*a* that the higher the NADH/NAD<sup>+</sup> ratio the higher the rate of H<sub>2</sub>O<sub>2</sub> formation at each NADH plus NAD<sup>+</sup> concentration. It is evident that the presence of NADH stimulated the H<sub>2</sub>O<sub>2</sub> generation at a given NAD<sup>+</sup> concentration. For example, the rate of H<sub>2</sub>O<sub>2</sub> generation with 250  $\mu$ M NAD<sup>+</sup> (without NADH) was  $0.16 \pm 0.02$  pmol/sec, but when the same amount of NADH was

also present [NADH/(NADH plus NAD<sup>+</sup>) ratio 0.5, at 500  $\mu$ M total NADH plus NAD<sup>+</sup> concentration], the rate was  $17.8 \pm 1.3$  pmol/sec. As expected, an increase in the NADH/NAD<sup>+</sup> ratio decreased the normal catalytic activity (i.e., NADH formation by the enzyme) (Fig. 6*b*). With 100  $\mu$ M NAD<sup>+</sup>, the enzyme is working close to its  $V_{\text{max}}$ , and a similar curve describes the rate of NADH formation measured at 500  $\mu$ M total [NADH plus NAD<sup>+</sup>]. Therefore, the decrease in the normal catalytic activity resulting from an increase in the NADH/NAD<sup>+</sup> ratio parallels an enhancement in H<sub>2</sub>O<sub>2</sub> generation. As shown in Table 1, the rate of NADH generation was 300 times larger than the rate of H<sub>2</sub>O<sub>2</sub> generation when only NAD<sup>+</sup> was present in the medium, whereas the rate of H<sub>2</sub>O<sub>2</sub> generation in the  $\alpha$ -KGDH catalyzed reaction increased by two orders of magnitude when the NADH/(NADH plus NAD<sup>+</sup>) ratio was 0.5 [total (NADH plus NAD<sup>+</sup>) was 500  $\mu$ M]. It is known that NADH undergoes slow autooxidation and small concentrations of H<sub>2</sub>O<sub>2</sub> are present in NADH solutions (Sawada and Yamazaki, 1973). In contrast, horseradish peroxidase is able to oxidize NADH at low pH with the concomitant formation of various oxidation–reduction intermediates in the active center of the enzyme (Yokota and Yamazaki, 1977). To rule out the possibility of artifacts in this study, control experiments were performed, and we found that the autooxidation of NADH in the presence of Amplex plus HRP is negligible compared with the oxidation in the presence of  $\alpha$ -KGDH plus Amplex plus HRP. In fact, the presence of Amplex Red inhibited the HRP-stimulated oxidation of NADH (data not shown).

#### The effect of Ca<sup>2+</sup> on the $\alpha$ -KGDH-mediated H<sub>2</sub>O<sub>2</sub> formation

Ca<sup>2+</sup> is known to be an important stimulator of the mitochondrial metabolism caused by activation of key dehydrogenases, among them,  $\alpha$ -KGDH (McCormack and Denton, 1979; Lukacs et al., 1988; Panov and Scarpa, 1996). This activation could be demonstrated in our experiments by measuring the NADH formation by the isolated  $\alpha$ -KGDH in the presence of different Ca<sup>2+</sup> concentrations (Fig. 7*b*). In the same concentration range (0–100  $\mu$ M), Ca<sup>2+</sup> significantly increased the rate of H<sub>2</sub>O<sub>2</sub> generation (Fig. 7*a*) both in the presence or absence of NAD<sup>+</sup>. These experiments were done in Mg<sup>2+</sup> and ADP-free medium to exclude an effect of Mg<sup>2+</sup> on the catalytic activity of the enzyme. The use of Mg<sup>2+</sup>-free medium explains the smaller catalytic activity of  $\alpha$ -KGDH (Panov and Scarpa, 1996) measured in these experiments and also the smaller rate of H<sub>2</sub>O<sub>2</sub> formation found in the absence of NAD<sup>+</sup>.

#### Discussion

This study demonstrates that  $\alpha$ -KGDH, a key NADH-generating enzyme in the Krebs' cycle, is able to produce ROS depending on the NADH/NAD<sup>+</sup> ratio present in the medium. The results clearly show that in the absence of the physiological electron acceptor NAD<sup>+</sup>, electrons from the substrate eventually reduce oxygen mediated by  $\alpha$ -KGDH. In contrast, with NADH, the en-

**Table 1. The rate of NADH and H<sub>2</sub>O<sub>2</sub> generation by  $\alpha$ -KGDH at different NADH/NADH plus NAD<sup>+</sup> ratios**

NADH/NAD <sup>+</sup> plus NADH	NADH generation (pmol/sec)	H <sub>2</sub> O <sub>2</sub> generation (pmol/sec)	NADH generation per H <sub>2</sub> O <sub>2</sub> generation
0	46 ± 2.8	0.15 ± 0.02	307
0.2	29.2 ± 2.3	2.58 ± 0.11	11.4
0.5	8.0 ± 0.19	17.8 ± 1.3	0.45

Experiments were performed as described for Figure 3, *a* and *c*, but NADH plus NAD<sup>+</sup> was applied in different ratios at 500  $\mu$ M NADH plus NAD<sup>+</sup> concentration.

Values are mean ± SEM from three experiments.

zyme produces H<sub>2</sub>O<sub>2</sub> without the need of the substrates. It is also demonstrated that in the presence of the substrates, an increase in the NADH/NAD<sup>+</sup> ratio, while inhibiting the physiological catalytic function of  $\alpha$ -KGDH, favors the ROS generation by the enzyme. In addition, Ca<sup>2+</sup>, which is a physiological activator of the enzyme, also activates the H<sub>2</sub>O<sub>2</sub> generation both in the absence and presence of NAD<sup>+</sup>.

$\alpha$ -KGDH is a complex enzyme catalyzing a key reaction in the Krebs' cycle:  $\alpha$ -ketoglutarate plus HS-CoA plus NAD<sup>+</sup> → succinyl-CoA plus CO<sub>2</sub> plus NADH. The enzyme consists of the following three subunits: E1, a thiamine pyrophosphate-dependent dehydrogenase; E2, dihydrolipoamide succinyltransferase; and E3, dihydrolipoamide dehydrogenase (Sheu and Blass, 1999). Because HS-CoA is required for the  $\alpha$ -KGDH-mediated H<sub>2</sub>O<sub>2</sub> formation, the reactions should proceed via E1 and E2 components of the enzyme, and H<sub>2</sub>O<sub>2</sub> is likely produced by the E3 subunit. Dihydrolipoamide dehydrogenase, the E3 component of  $\alpha$ -KGDH, is a flavoprotein. Generally, in the reaction catalyzed by flavoproteins, O<sub>2</sub> could be reduced to superoxide or H<sub>2</sub>O<sub>2</sub> (Kakinuma et al., 1987). However, with dehydrogenases, the overall reoxidation of reduced enzyme by O<sub>2</sub> is extremely slow, and the primary product is poorly defined (Massey, 1994). Superoxide production in the 2-oxo acid dehydrogenase reaction has been reported recently (Bunik and Sievers, 2002). The isolated lipoamide dehydrogenase was shown to exhibit NADH oxidase catalytic activity by which H<sub>2</sub>O<sub>2</sub> is produced (NADH plus H<sup>+</sup> plus O<sub>2</sub> → NAD<sup>+</sup> plus H<sub>2</sub>O<sub>2</sub>), and this reaction was accelerated by Zn<sup>2+</sup> (Gazaryan et al., 2002).

In the  $\alpha$ -KGDH-mediated reaction, both superoxide (data not shown) and H<sub>2</sub>O<sub>2</sub> could be detected, but it is not possible to determine whether both are produced in the enzyme reaction as described for some flavoproteins (Badwey and Karnovsky, 1979) or whether H<sub>2</sub>O<sub>2</sub> is generated by a very fast spontaneous dismutation of superoxide. It is most likely that both superoxide and H<sub>2</sub>O<sub>2</sub> are generated in the  $\alpha$ -KGDH-mediated reaction.

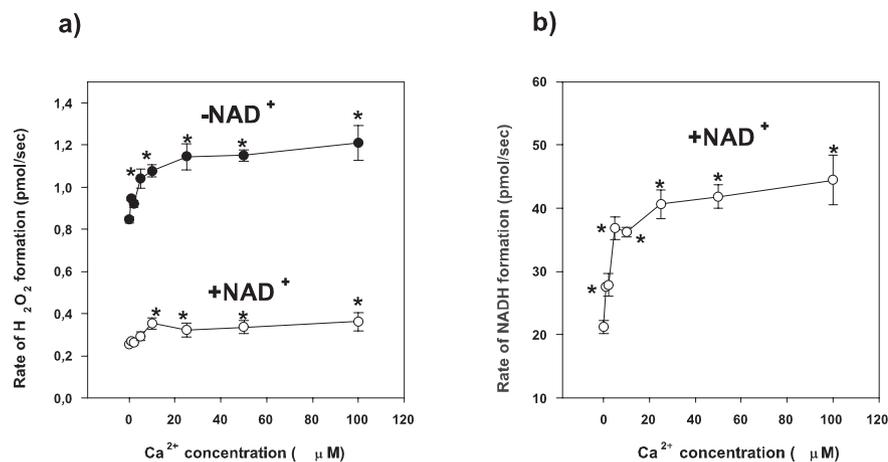

E3 is not unique to  $\alpha$ -KGDH but is present in the pyruvate dehydrogenase, branched chain  $\alpha$ -ketoacid dehydrogenase and glycine-cleavage system (Kochi et al., 1986). Our preliminary data, consistent with the results obtained by Starkov et al. (2004), show that H<sub>2</sub>O<sub>2</sub> is also generated in the pyruvate dehydrogenase reaction (data not shown), which reinforces the suggestion that H<sub>2</sub>O<sub>2</sub> is generated by the E3 subunit of  $\alpha$ -KGDH.

Our experiments indicate that reducing equivalents for ROS formation by the E3 subunit of  $\alpha$ -KGDH originate from substrate oxidation (forward reaction) when  $\alpha$ -KG and HS-CoA are present and, in the absence of NAD<sup>+</sup>, reduce O<sub>2</sub>. In contrast, reducing equivalents for E3 could also be provided by NADH (reverse reaction), in agreement with the reaction described for the isolated lipoamide dehydrogenase (Gazaryan et al., 2002). The isolated  $\alpha$ -KGDH (Sigma) used in our experiments is contaminated with pyruvate dehydrogenase subunits, among them, lipoamide dehydrogenase (Panov and Scarpa, 1996). This would not

interfere with our assay where  $\alpha$ -KG is the substrate, as established in a control assay where isolated pyruvate dehydrogenase was used (data not shown). When the effect of NADH was studied without  $\alpha$ -KG present, the lipoamide dehydrogenase may have had some contribution to the H<sub>2</sub>O<sub>2</sub> signal, consistent with the H<sub>2</sub>O<sub>2</sub> formation by lipoamide dehydrogenase (Gazaryan et al., 2002).

With the isolated enzyme, NAD<sup>+</sup> behaves as a switch accelerating the catalytic function of the enzyme by which the oxidation of  $\alpha$ -KG results in the production of NADH. In contrast, in the absence of NAD<sup>+</sup>, substrate oxidation leads to ROS generation. When the substrate oxidation is stimulated by Ca<sup>2+</sup>, ROS generation is also accelerated. At 1 mM  $\alpha$ -ketoglutarate concentration, the rate of ROS formation (1.05 ± 0.06 pmol H<sub>2</sub>O<sub>2</sub>/sec) is ~40 times slower than the rate of NADH generation (44 ± 4.1 pmol/sec) measured in the presence of NAD<sup>+</sup>. In the mitochondrial matrix where both NAD<sup>+</sup> and NADH are present, the NADH/NAD<sup>+</sup> ratio could determine the rate of ROS generation by  $\alpha$ -KGDH. This is indicated by the observation that H<sub>2</sub>O<sub>2</sub> formation mediated by the isolated enzyme was strongly dependent on the NADH/NAD<sup>+</sup> ratio. When the NADH/(NADH plus NAD<sup>+</sup>) ratio was >0.2, H<sub>2</sub>O<sub>2</sub> generation was significantly increased. With 500  $\mu$ M total NADH plus NAD<sup>+</sup> concentration, an increase in the NADH/(NADH plus NAD<sup>+</sup>) ratio from 0.2 to 0.5 resulted in a 6.9 times increase in the rate of H<sub>2</sub>O<sub>2</sub> generation by the isolated  $\alpha$ -KGDH (Table 1). At the same time, the normal catalytic function (i.e., the rate of NADH generation) decreased from 29.2 ± 2.3 to 8.0 ± 0.19 pmol/sec. It is clear from Table 1 that at 0.2 NADH/(NADH plus NAD<sup>+</sup>) ratio, the rate of NADH generation is 11.4 times higher than the rate of H<sub>2</sub>O<sub>2</sub> generation (29.2 ± 2.3 vs 2.58 ± 0.11 pmol/sec); however, when the NADH/(NADH plus NAD<sup>+</sup>) ratio is increased to 0.5, H<sub>2</sub>O<sub>2</sub> generation by the enzyme becomes highly significant. Therefore, NADH/NAD<sup>+</sup> ratio is critical to determine the rate of ROS formation in the reaction catalyzed by  $\alpha$ -KGDH. Because of differences of the methods, available values in the literature for the ratio of pyridine nucleotides in different tissues or in isolated mitochondria cover a wide range (Siess et al., 1976; Siess et al., 1977; Shiino et al., 1999). However, the physiological NAD<sup>+</sup> plus NADH concentration in isolated mitochondria appears to be in the millimolar range (Di Lisa et al., 2001). Data obtained from brain regions are consistent in indicating that the NADH/(NADH plus NAD<sup>+</sup>) ratio in the cortex, striatum, or hippocampus is ~0.2 (Klaidman et al., 1995); our measurements done with synaptosomes indicated somewhat higher values. However, these measurements could provide information only for the whole tissue, and values for *in situ* mitochondria are not available and would be very difficult to give. Assuming that the NAD<sup>+</sup> plus NADH concentration of *in situ* mitochondria is also in the millimolar range, and given the tendency shown in Figure 6, it can be suggested that an increase in the NADH/NAD<sup>+</sup> ratio at this NAD<sup>+</sup> plus NADH concentration could be even more significant in stimulating the H<sub>2</sub>O<sub>2</sub> generation by  $\alpha$ -KGDH.

ROS generation by  $\alpha$ -KGDH in isolated mitochondria is demonstrated by Starkov et al. (2004), and results shown in our study indicate that it occurs also in the *in situ* mitochondria within isolated nerve terminals. The amount of ROS generated *in situ* is sufficient to inhibit endogenous aconitase (Fig. 1). We reported previously that  $\alpha$ -KGDH activity of *in situ* mitochondria in synaptosomes was 14.2 nmol/min/mg synaptosomal protein (Tretter and Adam-Vizi, 2000). Assuming that this activity is 300 times higher than the rate of H<sub>2</sub>O<sub>2</sub> production (derived from data obtained in this study with the isolated enzyme; 46 ± 2.8 pmol

**Figure 7.** *a, b*, The effect of free  $[Ca^{2+}]$  on the  $H_2O_2$  (*a*) and NADH formation (*b*) measured with isolated  $\alpha$ -KGDH. Isolated  $\alpha$ -KGDH was incubated in a buffer containing different concentrations of ionized  $Ca^{2+}$  (0–100  $\mu M$ ).  $Ca^{2+}$  concentrations were controlled as described in Materials and Methods. The experimental protocol was as described for Figure 3, but ADP and  $Mg^{2+}$  were not present in the medium.  $H_2O_2$  formation was measured in the absence (●) or presence (○) of  $NAD^+$  (1 mM). Values represent mean  $\pm$  SEM from three experiments. Asterisk indicates points significantly different from the control (measured in the absence of  $Ca^{2+}$ ).

NADH/sec vs  $0.15 \pm 0.02$  pmol  $H_2O_2$ /sec),  $H_2O_2$  generation mediated by  $\alpha$ -KGDH in synaptosomes could be  $\sim 50$  pmol/min/mg. This is likely to be an underestimated value; when  $NAD^+$  and NADH were present, the rate of  $H_2O_2$  generation mediated by the isolated  $\alpha$ -KGDH was more significant.

The strong dependence of the  $H_2O_2$  formation by  $\alpha$ -KGDH on the  $NADH/NAD^+$  ratio has important physiological implications. When the reoxidation of NADH in the respiratory chain is impaired, the  $NADH/NAD^+$  ratio in the mitochondrial matrix is increased, thus inhibiting the  $NAD^+$ -dependent dehydrogenases (Gomazkova and Krasovskaia, 1979; Lawlis and Roche, 1980). Under this condition, ROS production in the  $\alpha$ -KGDH catalyzed reaction could become significant, contributing to the accumulation of ROS in cells. In particular, inhibition of complex I is important in this respect, because this is characteristically present in the degenerating substantia nigra obtained postmortem from patients suffering from Parkinson's disease (Schapira et al., 1989, 1990), and inhibition of complex I *in vivo* induces Parkinsonian syndromes (Betarbet et al., 2000). The experimental model of inhibition of complex I using rotenone revealed an enhanced  $H_2O_2$  generation in both isolated (Votyakova and Reynolds, 2001) and *in situ* mitochondria present in isolated nerve terminals (Sipos et al., 2003), which was attributed to ROS generation at complex I in the respiratory chain. Given the observations in the present study, it is suggested that the stimulated ROS production caused by complex I inhibition could be attributed to, at least in part, the increased  $NADH/NAD^+$  ratio stimulating ROS generation in the  $\alpha$ -KGDH-mediated reaction.

There are a few cases in which genetic defects of  $\alpha$ -KGDH in humans have been reported (Gibson et al., 2000). When the E3 component was deficient, patients suffered from a progressive neural degeneration (Kohlschutter et al., 1982), pointing to a possible role of  $\alpha$ -KGDH deficiency in the pathogenesis of neurodegenerative diseases. This enzyme was found to be inhibited in postmortem brain tissues from patients who suffered from Parkinson's or Alzheimer's disease (Gibson et al., 1988; Mizuno et al., 1990, 1994; Mastrogicola et al., 1996). It is tempting to speculate that with a deficient  $\alpha$ -KGDH, in particular involving the E3 component,  $H_2O_2$  generation by the enzyme could be-

come dominant while losing a large part of the normal catalytic activity.
