Activation of the hippocampus is required to encode memories for new events (or episodes). Observations from animal studies suggest that, for these memories to persist beyond 4–6 h, a release of dopamine generated by strong hippocampal activation is needed. This predicts that dopaminergic enhancement should improve human episodic memory persistence also for events encoded with weak hippocampal activation. Here, using pharmacological functional MRI (fMRI) in an elderly population in which there is a loss of dopamine neurons as part of normal aging, we show this very effect. The dopamine precursor levodopa led to a dose-dependent (inverted U-shape) persistent episodic memory benefit for images of scenes when tested after 6 h, independent of whether encoding-related hippocampal fMRI activity was weak or strong (U-shaped dose–response relationship). This lasting improvement even for weakly encoded events supports a role for dopamine in human episodic memory consolidation, albeit operating within a narrow dose range.

Introduction

Converging evidence from animal studies suggests that dopamine critically contributes to the cellular consolidation of hippocampal-dependent memories by inducing protein synthesis in hippocampal neurons (Frey and Morris, 1997; O'Carroll et al., 2006). Behavioral evidence from episodic-like memory paradigms in animals show that the availability of dopamine within the hippocampus during encoding is necessary for long-lasting memories (4–6 h and longer) but does not influence memory across short delays (30 min) (Bethus et al., 2010). Consequently, weakly encoded events not leading to dopamine release in the hippocampus can be recollected after short delays but are forgotten after delays of 6 h and longer (O'Carroll et al., 2006; Bethus et al., 2010). Testing for a similar role in human episodic memory requires manipulation of dopamine levels at encoding with subsequent testing of memory after both short and long retention intervals (Wang and Morris, 2010; Lisman et al., 2011).

A key prerequisite for characterizing the role of dopamine in human episodic memory consolidation is to relate the effects of dopamine to the strength of hippocampal activation at encoding.

This is because the hippocampal release of dopamine can be enhanced by strong hippocampal activation (for review, see Lisman et al., 2011). If increasing dopamine levels in humans improves memory performance after long delays through similar mechanisms to that seen in animal studies (O'Carroll et al., 2006; Bethus et al., 2010), dopamine administration should improve long-term memory for events that elicit only weak hippocampal activity at encoding, events that normally would be associated with low levels of hippocampal dopamine. This predicts that increasing availability of dopamine would decrease the influence of hippocampal activation at encoding, measured using fMRI on delayed memory.

Here we tested these hypotheses among healthy older adults in a pharmacological fMRI study. We chose an elderly population as our target group for two reasons. First, understanding the role of dopamine in episodic memory is of particular relevance in old age when a decline in episodic memory is well recognized (Light, 1991; Buckner, 2004; Hedden and Gabrieli, 2004). Second, there is known age-dependent degeneration of substantia nigra/ventral tegmental area (SN/VTA) dopamine neurons (Fearnley and Lees, 1991; Bäckman et al., 2006). Consequently, we recruited 32 healthy older adults who participated in a double-blind crossover study with the dopamine-precursor levodopa (L-DOPA) and placebo. Participants performed an fMRI encoding task in which they viewed indoor and outdoor scenes and episodic memory for these scenes was tested after 2 h (“early test”) or 6 h (“delayed test”) (Fig. 1). We used an additional manipulation of reward as a way of manipulating endogenous mechanisms of dopamine-related memory enhancement and to compare its effect on memory consolidation with the exogenous manipulation through the administration of L-DOPA. Thus, half the stimuli were probabilistically associated with reward and half with no reward. To ac-

Figure 1. Study timeline and tasks. In the fMRI scanner, participants viewed randomly presented images of scenes and were required to indicate whether they were indoor or outdoor scenes with a button press. A total of 80% of correct responses for one category were followed by a reward (£1.00) and for the other category was followed by a neutral outcome (£0.00), thereby the images served as reward-predicting and neutral cues, respectively. Following this outside the scanner, memory for half the scenes were tested 2 h after encoding (early) and the remaining scenes 6 h after encoding (delayed) using a remember/know paradigm.

count for the possibility that the effect of L-DOPA may depend on the structural integrity of the SN/VTA in our older participants, we used a semiquantitative MR imaging technique called magnetization transfer (MT) imaging (Wolff and Balaban, 1989; Helms et al., 2009). It is known that the cognitive effects of dopamine are dose dependent (Knecht et al., 2004), often showing a nonlinear dose–response curve (Goldman-Rakic et al., 2000; Cools et al., 2001; Li and Sikström, 2002; Takahashi et al., 2008). To account for such a possibility also in episodic memory, we conducted planned correlations between body-weight-adjusted relative doses of L-DOPA and our behavioral and encoding-related functional outcomes measures.

Materials and Methods

Participants

We recruited participants via our departmental website, advertisement in local public buildings, and word of mouth. To ensure participants were healthy, volunteers were initially screened by telephone and excluded if they had any of the following: (1) current or past history of neurological, psychiatric, or endocrinological disorders (including diabetes mellitus and thyroid dysfunction); (2) metallic implants; (3) tinnitus; (4) major visual impairment; and (5) history of drug addiction. To control for vascular risk factors, individuals known to have had a stroke or transient ischemic attack, myocardial infarction, or require more than one anti-hypertensive medication were not eligible for participation. All participants had a Mini-Mental State Examination score ≥ 28 and a Geriatric Depression Scale score ≤ 7 (a score > 11 would indicate depression). All participants performed within 1.5 SD of age-related norms on a range of neuropsychological tests, ensuring that they were cognitively intact as follows: Rey Auditory and Verbal Learning Test (RAVLT) trials 1–5 (mean $\pm$ SD, 50.2 $\pm$ 8.3), RAVLT trial 7 (mean $\pm$ SD, 9.5 $\pm$ 2.3), D2 cancellation test of attention (mean $\pm$ SD, 152.3 $\pm$ 33.5), Digit Span Forward (median, 8; range, 4–9), Digit Span Backward (median, 5; range, 3–8), Controlled Oral Word Association test (COWA) phonemic fluency (mean $\pm$ SD, 58.0 $\pm$ 14.0), COWA semantic fluency (mean $\pm$

SD, 26.5 $\pm$ 6.6), and Visual and Object Space Perception number location (median, 10; range, 8–10). All subjects had a normal neurological examination (performed by a neurologist, R.C.), ensuring that participants did not have concurrent undiagnosed neurological conditions. Written informed consent was obtained from all participants. The study received ethical approval from the North West London Research Ethics Committee 2.

Participants in the current study ($n = 32$) were selected from a larger sample of 42 healthy older adults 65–75 years old, who had participated in a previous study within the preceding 6 months. Preselection was based on an assessment of MT values of the SN/VTA. MT imaging is a semiquantitative MR imaging technique that reflects structural integrity (Wolff and Balaban, 1989) in which lower MT values suggest less structural integrity (Eckert et al., 2004; Düzel et al., 2008). Ten individuals with MT values of the SN/VTA scattered around the mean MT values of the group were excluded to increase the variance in the sample, resulting in 16 participants with higher MT values (“high integrity” group) and 16 with lower MT values (“low integrity” group). Note that the current cohort still had a normal distribution of midbrain integrity in both the final subset of participants for the behavioral analysis ($n = 29$, Kolmogorov–Smirnov test statistic = 0.11, $p = 0.200$) and the fMRI analysis ($n = 23$, Kolmogorov–Smirnov test statistic = 0.093, $p = 0.200$). The two MT groups were matched for age (independent t test, $p = 0.208$) and closely matched for gender (low group 12 females, high group 9 females; Mann–Whitney U test, $p = 0.272$).

Three subjects were excluded from all analyses. Of these, two were excluded because of poor performance in the encoding task ($< 60\%$ correct indoor/outdoor judgment) resulting from side-effects of L-DOPA (vomiting during the encoding task) or misunderstanding the task instructions. One other participant misunderstood the instructions for the first remember/know test and was excluded from all analyses. With regards to side-effects of L-DOPA, four subjects vomited, of whom one was excluded as noted above. For the other three participants, this brief side-effect occurred after the encoding task had been completed and their encoding performance was $> 98\%$ correct; thus, we did not exclude them from our analyses.

Study procedure

We used a double-blind placebo controlled crossover design. Participants attended on two occasions, 1 week apart, and performed the same task on both days, 90 min after ingestion of either levodopa (150 mg of levodopa + 37.5 mg of benserazide mixed in orange juice; L-DOPA) or placebo (orange juice alone), the order of which was counterbalanced. Benserazide promotes higher levels of dopamine in the brain while minimizing peripheral side-effects such as nausea and vomiting. We chose a dose of 150 mg because a previous study has shown that, although 100 mg can improve verbal learning in younger adults, those with a lower body weight who effectively received higher doses showed a greater effect (Knecht et al., 2004). To achieve comparable drug absorption across individuals, subjects were instructed not to eat for up to 2 h before commencing the study. Repeated physiological measurements were recorded on both days before and after the pharmacological manipulation, which showed a reduction in blood pressure from baseline to 90 min after L-DOPA (from average of 148/82 to 142/80; paired *t* tests: systolic, $t = 3.12$, $p = 0.004$; diastolic, $t = 2.46$, $p = 0.020$) but no change in heart rate. Subjective mood rating scales were also recorded. This series of 16 visual analog scales collapsed down to measure three factors: how alert, content, and calm participants felt (Bond and Lader, 1974). When baseline levels were taken into account, there was no significant difference in these subjective mood rating scales at encoding after receiving L-DOPA compared with placebo. For the early and delayed memory tests, the only significant difference was at early test in which participants felt more content on the day they received L-DOPA compared with placebo (mean $\pm$ SD difference in scores 5.06 ± 11.1 ; paired *t* test, $t = 2.37$, $p = 0.027$).

fMRI encoding task

We presented participants with 120 grayscale images of indoor ($n = 60$) and outdoor ($n = 60$) scenes in a randomized manner (Fig. 1). Different images were used on each of the two test days. Participants were required to indicate with a button press whether the image was of an indoor or outdoor scene (response required within 2 s). After a brief delay (fixation cross, 1.5 s), this was followed by either a reward (indicated by £1.00) or neutral outcome (indicated by £0.00) (outcome, 1 s) and finally an additional fixation cross (3 s). A total of 80% of correct responses for each category of scenes predicted either a reward or no reward. For each participant, which category predicted reward (indoor or outdoor) was different on the two test days, and this order was counterbalanced across subjects.

Before pharmacological administration, participants were familiarized with the encoding task through 10 practice trials using different images. During this practice task, the outcome was not probabilistic. Participants were told which category (indoor or outdoor) would be rewarded, with this category remaining the same for the study task. The purpose of this was to ensure, by the time participants performed the task in the scanner, that they would anticipate a reward when they saw images in the rewarded category (thus serving as reward predicting cues) and vice versa for the unrewarded category (serving as neutral cues).

Participants were given written and verbal task instructions that included the following: “pay attention to all the images presented as we may return to some of them later in the day.” This same instruction was given on both days without being explicitly told on the second day that they would be performing memory recognition tasks again to minimize practice effects. After completion of the encoding task, participants immediately went on to have additional scanning to acquire diffusion tensor images on one day (not reported here) or were asked to sit alone in a room for an equivalent amount of time and not perform any activities on the other day. All participants also completed a brief unrelated decision-making task before performing the encoding task on both days (not reported here).

Behavioral recognition tasks

We tested memory for scenes shown during the fMRI encoding task behaviorally 2 and 6 h after encoding (henceforth referred to as the early and delayed test, respectively) using a remember/know paradigm. For the early test, participants were shown a random selection of half of the

scenes they had viewed previously during the encoding task (30 indoor and 30 outdoor scenes) and 30 new distractor scenes (15 indoor and 15 outdoor). Memory for the remaining scenes intermixed with another set of 30 new distractor images was tested at the delayed test. For both tests, while the scene was displayed, participants indicated with a button press whether the image was old (seen before during the encoding task) or new (never seen before) (maximum reaction time of 6 s). We also asked for a second decision in relation to the stimuli (maximum reaction time of 6 s): if they chose “old” then participants had to commit to one of three additional options: remember, know, or guess, in which “remember” indicated they could recollect something specific about the study episode. If the image was confidently familiar but they had no recollective experience, they were instructed to choose “know.” Guess responses were given when unsure whether the image was old. If participants indicated the picture was “new,” then an additional decision was made of whether they were sure or had guessed. Remember responses are thought to reflect hippocampal-dependent episodic memory recollection, whereas know responses index familiarity (Yonelinas et al., 2002).

We chose to perform the early test of memory 2 h after encoding (3.5 h after L-DOPA/placebo administration) to minimize the potential confounding factor of persisting drug effects at early but not delayed test. Thus, we were able to test participants' memory on two occasions after a short and long interval, ensuring they were not under the peak effects of L-DOPA on both occasions, while still allowing a sufficient time window between the tests to investigate our hypothesis that L-DOPA modulated consolidation (4–6 h after encoding). We acknowledge that, by performing the early test of memory after a 2 h delay, the consolidation process may have already begun, but we would expect the effects to be less pronounced than at delayed test.

Behavioral analyses

For the encoding task, we calculated the percentage of correct indoor and outdoor responses and reaction times for these responses. For the early and delayed memory tests, hit rates were calculated as a proportion of correctly encoded items for the condition of interest. Corrected hits were calculated as follows: correct old responses – old responses for new items (false alarms). We then separated this into corrected remember hits (remember responses for correct old items – remember responses for false alarms) and corrected know hits (know responses for correct old items – know responses for false alarms). Corrected hit rates were calculated for the following conditions: (1) reward-predicting scenes at early test on placebo; (2) neutral scenes at early test on placebo; (3) reward-predicting scenes at early test on L-DOPA; (4) neutral scenes at early test on L-DOPA; (5) reward-predicting scenes at delayed test on placebo; (6) neutral scenes at delayed test on placebo; (7) reward-predicting scenes at delayed test on L-DOPA; and (8) neutral scenes at delayed test on L-DOPA. Although all analyses were performed using corrected hit rates, we also report uncorrected hit rates and false alarms, d' , and response bias for completeness. d' and response bias were calculated using standard Excel formula (Stanislaw and Todorov, 1999). We analyzed hit rates using a $2 \times 2 \times 2$ mixed ANOVA with drug (L-DOPA/placebo), time of test (early/delay), and reward (reward-predicting scenes/neutral scenes) as the within-subjects factors, and SN/VTA integrity group indexed by MT values (low integrity/high integrity) as a between-subjects factor.

Given evidence of an inverted U-shaped relationship between dopamine and working memory, we hypothesized a similar relationship for episodic memory. Because the effective dose of L-DOPA is dependent on body weight (Zappia et al., 2002), we calculated the weight-adjusted dose for each participant (150 mg/body weight, mg/kg). We then performed regression analyses using both linear and quadratic models, in which corrected remember and know hit rates were the dependent variable and the weight-adjusted dose of L-DOPA was the independent variable.

We also grouped participants into three “dose groups” (referred to as low-, middle-, and high-dose groups). We note that, within these groupings, there were no significant differences in health-related variables or neuropsychological test performance as follows: (1) years of education (one-way ANOVA, $F = 0.364$, $p = 0.698$); (2) blood pressure ($F = 2.120$, $p = 0.139$); (3) smoking status ($F = 0.225$, $p = 0.800$); (4) cholesterol status ($F = 1.465$, $p = 0.250$); (5) IQ ($F = 0.316$, $p = 0.732$); (6) RAVLT

trials 1–5 ($F = 0.352$, $p = 0.707$); (7) RAVLT trial 7 ($F = 1.302$, $p = 0.290$); (8) D2 cancellation test of attention ($F = 0.738$, $p = 0.488$); (9) Forward Digit Span ($F = 3.17$, $p = 0.066$); (10) Backward Digit Span ($F = 2.096$, $p = 0.143$); (11) phonemic fluency ($F = 0.045$, $p = 0.956$); (12) semantic fluency ($F = 0.023$, $p = 0.977$); and (12) Visual and Object Space Perception ($F = 0.379$, $p = 0.689$).

We report results significant at the threshold $p < 0.05$. All significance tests are two tailed.

Neuroimaging

All imaging was acquired using a 3.0 T Trio MRI scanner (Siemens) with a 32-channel head coil.

Anatomical MRI data acquisition. A structural multi-parameter map protocol using a 3D multi-echo fast low-angle shot (FLASH) sequence at 1 mm isotropic resolution (Helms et al., 2008b) was used to acquire MT-weighted images [echo time (TE), 2.2–14.70 ms; repetition time (TR), 23.7 ms; flip angle (FA), 6°], T1-weighted images (TE, 2.2–14.7 ms; TR, 18.7 ms; FA, 20°), and proton-density-weighted images (TE, 2.2–19.7 ms; TR, 23.7 ms; FA, 6°) (Helms et al., 2008b). B1 mapping (TE, 37.06 and 55.59 ms; TR, 500 ms; FA, 230°–10:130°; 4 mm³ isotropic resolution) was acquired to correct the T1 maps for inhomogeneities in the transmit radiofrequency field (Lutti et al., 2010). A double-echo FLASH sequence (TE1, 10 ms; TE2, 12.46 ms; 3 × 3 × 2 mm resolution; 1 mm gap) was used to measure local field inhomogeneities and correct for the image distortions in the B1 mapping data. Using in-house code, quantitative MT maps were extracted for each subject (Helms et al., 2008a).

fMRI data acquisition. Functional data were acquired for each subject on both test days. On each day, two fMRI time series were acquired containing 148 volumes (matrix size, 64 × 74; 48 slices; image resolution, 3 × 3 × 3 mm; FOV, 192 × 222 mm; TR, 70 ms; TE, 30 ms). The fMRI acquisition protocol was optimized to minimize susceptibility-induced BOLD signal losses in inferior frontal and temporal lobe regions (Weiskopf et al., 2006). Six additional volumes at the beginning of each series were acquired to allow for steady-state magnetization and were subsequently discarded. Individual field maps were recorded using a double-echo FLASH sequence (matrix size, 64 × 64; 64 slices; spatial resolution, 3 × 3 × 3 mm; 1 mm gap; short TE, 10 ms; long TE, 12.46 ms; TR, 1020 ms) for distortion correction of the acquired EPI images. Using the FieldMap toolbox, field maps were estimated from the phase difference between the images acquired at the short and long TE.

fMRI data preprocessing. Data were analyzed using Statistical Parametric Mapping software (SPM8, Wellcome Trust Centre for Neuroimaging, www.fil.ion.ucl.ac.uk/spm). Bias correction (part of the Segmentation step in SPM8) was performed because fMRI data acquired with a 32-channel head coil may be prone to strong intensity inhomogeneities. Pre-processing then included realignment, unwarping using individual field maps, co-registration, and spatial normalization to the Montreal Neurological Institute (MNI) space. For normalization, we used unified segmentation to classify anatomical T1-weighted images into gray matter, white matter, and CSF (Ashburner and Friston, 2005), followed by the diffeomorphic registration algorithm (DARTEL) to generate flow fields to warp EPI images to MNI space (Ashburner, 2007). Finally, data were smoothed with a 6 mm FWHM Gaussian kernel. The fMRI time series data were high-pass filtered (cutoff, 128 s) and whitened using an autoregressive(1) model. For each subject, a statistical model was computed by applying a canonical hemodynamic response function combined with time and dispersion derivatives.

fMRI data analyses. Statistical analyses were performed using the general linear model (GLM) approach. We used a subsequent memory analysis whereby neural activity at encoding was contrasted for items that were subsequently remembered or forgotten. We built two different GLMs at the first level, the first of which was to determine the overall subsequent memory effect for all “recognized” items, and a second model, more specific to our behavioral results, to determine the subsequent memory effect for items later “remembered,” in particular for neutral items. We collapsed together responses at early and delayed recall to increase statistical power. For the same reason, we excluded participants who had <10% of trials in either the remember plus know, remem-

ber, or forget categories to ensure that analyses were statistically robust. Thus, whereas GLM 1 involved all 29 participants, GLM 2 included data from 23 participants (note the order of L-DOPA/placebo administration remained counterbalanced for this subset, in which 11 participants received L-DOPA on day 1 and 12 participants received L-DOPA on day 2). At the first-level analysis, separate design matrices for L-DOPA and placebo were constructed.

GLM 1: recognized (remember plus know) versus forgotten. At the first level, the design matrix consisted of regressors at the onset of the image presentation for reward-predicting scenes and neutral scenes. These encoding-related responses were modeled separately for items subsequently recognized (correct old responses, thus collapsing both remember and know responses together) and forgotten (incorrect new responses). Thus, the following were the main regressors of interest: (1) correct old response for neutral scenes (recognized); (2) correct old response for reward-predicting scenes (recognized); (3) incorrect new response for neutral scenes (forgotten); and (4) incorrect new response for reward-predicting scenes (forgotten).

Separate regressors at the time of the outcome for a win (in which participants saw £1.00 on the screen) and no win (in which participants saw £0.00) outcomes were included. We included a regressor of no interest for errors when participants failed to press the correct button to indicate whether the image was of an indoor or outdoor scene. To capture residual movement-related artifacts, six covariates (the three rigid-body translation and three rotations resulting from realignment) were also included as regressors of no interest. Finally, we also included 18 regressors for cardiac and respiratory phases to correct for physiological noise (Glover et al., 2000; Birn et al., 2006). At the first level, we implemented a contrast for the main effect of memory (recognized > forgotten).

GLM 2: remember versus forgotten. Our behavioral results identified a specific effect of L-DOPA on episodic memory indexed by remember responses. On this basis, we performed another analysis in which we divided correct old responses into remember and know responses and modeled them as separate regressors.

Thus, the following constituted the main regressors of interest: (1) correct remember response for neutral scenes (remember); (2) correct remember response for reward-predicting scenes (remember); (3) correct know response for neutral scenes (know); (4) correct know response for reward-predicting scenes (know); (5) incorrect new response for neutral scenes (forgotten); and (6) incorrect new response for reward-predicting scenes (forgotten).

All other regressors of no interest used in the previous design were also included in this model. We were then able to contrast remember > forgotten responses at the first level for both rewarded and neutral items together and for neutral items alone.

Because we were predominantly interested in the effect of L-DOPA on memory, for both GLM 1 and GLM 2, contrast images were entered into a paired *t* test design at the second level. We were then able to examine the main effect of memory and the interaction between memory and drug (L-DOPA > placebo and placebo > L-DOPA) using *T* contrasts.

Based on an a priori hypothesis that dopamine promotes hippocampal consolidation, we built a functional region of interest (ROI) that included those voxels within the hippocampus that were more active for remembered when compared with forgotten items. We extracted parameter estimates within these voxels using the MarsBaR toolbox (Brett et al., 2002) and entered them in a 2 (remember/forgotten) × 2 (L-DOPA/placebo) ANOVA. With this approach, we were able to test for the effects of drug on the selected voxels. Note that the drug effects are orthogonal to the main effect of memory used to define the functional ROI.

Anatomical masks

We created anatomical masks averaged across our study participants to use for small-volume correction (SVC) and to anatomically constrain functional ROIs from which parameter estimates were extracted. Our motivation for this was to account for age-related structural brain changes to try to lend greater accuracy to our analyses. The automated recon-all pipeline of Freesurfer (version 4.5.0, <http://surfer.nmr.mgh.harvard.edu/>) was used to parcellate the hippocampus (Fischl et al.,

Table 1. Demographic details for participants

Age (years)	70.31 (3.22)
Gender (male/female)	10/19
Education (years)	16.00 (2.63)
National Adults Reading Test IQ	121.38 (6.58)
Body mass index	26.8 (4.45)
Non-smoker	28 (96.6%)
Normotensive	27 (93.1%)
Mini-Mental State Examination	30 (28–30)
Geriatric Depression Scale	1 (0–7)

Results are mean (SD), number (%), or median (range).

2004). The high level of gray/white matter contrast on MT images was exploited to manually segment the SN/VTA for each subject, performed by a trained individual (R.C.) as per Düzel et al. (2008) using MRIcro (Rorden and Brett, 2000). Individual subjects' hippocampal and SN/VTA masks were warped to MNI space using DARTEL as described previously. A group-averaged mask was made from these warped images. For the bilateral hippocampus, we used 22 subjects' masks, in which subjects were excluded because of preprocessing errors ($n = 6$) or inaccurate segmentation after visual inspection ($n = 1$). For the bilateral SN/VTA, all subjects' masks were used.

Statistics. Clusters were defined using a threshold of $p < 0.001$ and > 10 voxels. We report results corrected for multiple comparisons across the whole brain or after SVC for the bilateral hippocampus and bilateral SN/VTA using familywise error correction (FWE) at a threshold of $p < 0.05$. We selected the hippocampus and SN/VTA a priori for SVC given evidence for a functional SN/VTA–hippocampal circuit underlying the dopaminergic modulation of episodic memory (Lisman and Grace, 2005; Lisman et al., 2011). Imaging results are overlaid on a group-average MT image because the high level of gray/white matter allows good visualization of both of our main ROIs (hippocampus and SN/VTA).

Nonlinear modulation of neural activity by dopamine. We tested whether neural activity was also modulated in a nonlinear (i.e., quadratic) manner by L-DOPA. We performed regression analyses using the parameter estimates from functionally activated clusters found in the hippocampus. In these models, parameter estimates were the dependent variable and the weight-adjusted dose of L-DOPA was the independent variable. A similar regression analysis was performed using MT values of the SN/VTA rather than L-DOPA dose.

Results

Encoding performance

Demographic data for 29 of the 32 healthy older adults who participated are shown in Table 1. Accuracy for button presses for indoor and outdoor images during encoding was high (mean $\pm$ SD correct responses, $97.6 \pm 2.99\%$). Accuracy was not affected by L-DOPA and reward (main effect of reward, $F_{(1,29)} = 3.67$, $p = 0.07$; main effect of drug, $F_{(1,29)} = 3.62$, $p = 0.07$; reward $\times$ drug interaction, $F_{(1,29)} = 0.15$, $p = 0.71$), nor was reaction time (main effect of reward: $F_{(1,29)} = 2.44$, $p = 0.13$; main effect of drug: $F_{(1,29)} = 0.58$, $p = 0.45$; reward $\times$ drug interaction: $F_{(1,29)} = 0.012$, $p = 0.91$).

Dose-dependent enhancement of memory by L-DOPA

All analyses were performed using corrected hit rates (hits – false alarms as a proportion of correctly encoded trials, for the condition of interest). A summary of uncorrected hit rates and false alarms, d' , and response bias are provided in Tables 2 and 3, respectively.

The ability to recognize old (i.e., previously encoded) items and reject new items was better at early compared with delayed test as shown by a main effect of time ($F_{(1,27)} = 9.505$, $p = 0.005$) in a 2 (drug: L-DOPA/placebo) $\times$ 2 (time of test: early/delay) $\times$ 2 (reward: reward-predicting scenes/neutral scenes) repeated-measures ANOVA with structural integrity of the SN/VTA (low

integrity/high integrity) as a between-subjects factor. There was also a time $\times$ reward interaction ($F_{(1,27)} = 48.289$, $p = 0.000$). Here *post hoc* tests showed that, for reward-predicting images, corrected hit rates were higher at early compared with delayed test (paired t test, $t_{(28)} = 7.178$, $p = 0.000$) with no difference evident for neutral items ($t_{(28)} = 1.201$, $p = 0.240$). There was no main effect of drug ($p = 0.530$) and no interactions with drug (drug $\times$ time: $p = 0.797$; drug $\times$ reward: $p = 0.250$; drug $\times$ time $\times$ reward: $p = 0.254$). Furthermore there were no significant interactions with SN/VTA structural integrity (integrity group $\times$ drug: $p = 0.169$; integrity group $\times$ reward: $p = 0.780$; integrity group $\times$ time of test: $p = 0.664$). We next performed a planned assessment of the potential dose-dependent effect of L-DOPA using regression analyses with the weight-adjusted dose of L-DOPA (150 mg/body weight, mg/kg) and corrected remember and know hit rates for each condition separately (Table 4). Remember hit rates for neutral images at early test showed a significant quadratic and linear regression, explaining 28% ($p = 0.014$) and 22% ($p = 0.011$) of the variance, respectively. At delayed test, there was a significant quadratic regression alone, in which the weight-adjusted dose of L-DOPA explained 29% ($p = 0.013$) of variance in an inverted U-shaped pattern (Fig. 2a). In contrast, L-DOPA dose did not predict remember hit rates for the rewarded scene category, nor did it predict know hit rates for any condition. This points to a modulatory effect of L-DOPA on episodic memory for neutral items.

To further assess whether L-DOPA enhanced memory recollection for neutral scenes, we subtracted hit rates on placebo from those on L-DOPA. To visualize this memory performance difference between L-DOPA and placebo and to quantify the dose of L-DOPA that boosted memory, we ranked subjects based on the weight-adjusted L-DOPA dose they received and divided our cohort into three groups as follows: (1) low-dose group ($n = 10$), who received an average of 1.7 mg/kg L-DOPA; (2) middle-dose group ($n = 9$), who received an average of 2.0 mg/kg; and (3) high-dose group ($n = 10$), who received an average of 2.5 mg/kg. Here we saw that, for delayed recall of neutral items, memory performance in the middle-dose group was higher on L-DOPA than on placebo (one-sample t test, $t_{(8)} = 2.767$, $p = 0.024$) (Fig. 2b). Performance in the low- and high-dose groups did not differ between drug or placebo ($p = 0.083$ and $p = 0.147$, respectively). Performance was significantly different between all three groups (one-way ANOVA, $F_{(2,26)} = 7.803$, $p = 0.002$; low vs middle group, $p = 0.007$; middle vs high group, $p = 0.005$). This demonstrates that, within the inverted U-shaped relationship between L-DOPA and episodic memory, L-DOPA significantly enhanced memory performance within a relatively narrow dose range. We note that individual drug-minus-placebo difference scores did not show a significant quadratic correlation with L-DOPA weight-adjusted dose ($F_{(2,26)} = 2.518$, $p = 0.100$), presumably because the difference scores were more noisy than the behavioral scores under the drug.

In contrast, at early test, performance did not differ between L-DOPA and placebo for the middle- and high-dose groups, and participants in the low-dose group performed better on placebo than L-DOPA (one-sample t test, two-tailed: low, $t_{(9)} = -3.097$, $p = 0.013$; middle, $t_{(8)} = 1.356$, $p = 0.212$; high, $t_{(9)} = 0.429$, $p = 0.678$). There was no significant between-group differences either (one-way ANOVA, $F_{(2,28)} = 3.027$, $p = 0.066$). Overall these results demonstrate that the beneficial effect of L-DOPA on episodic memory was more robust at delayed than early testing.

Modulation of memory performance for neutral items at delayed test by L-DOPA was attributable to an effect on hits rather

than false alarms. This was demonstrated by a significant three-way interaction between drug (L-DOPA/placebo), memory performance (remember hits/false alarms), and dose group (low/middle/high) ($F_{(1,26)} = 7.80$, $p = 0.002$). As shown in Figure 3, *post hoc* tests showed a selective increase in remember hits in the middle-dose group compared with the high-dose group ($t = 2.36$, $p = 0.031$) and a trend toward increased remember hits in the middle-dose group compared with the low-dose group ($t = 1.97$, $p = 0.065$), with no difference in false alarm rates between groups.

Order effects

To assess for order effects, we performed a repeated-measures ANOVA across all responses (remember plus know corrected hit rates) with drug (L-DOPA/placebo), time of test (early/delayed), and reward (reward-predicting scenes/neutral scenes) as within-subjects factors, and L-DOPA dose group (low/middle/high) and order (L-DOPA day 1/L-DOPA day 2) as between-subjects factors. This showed no significant interactions with order (drug $\times$ order, $p = 0.183$; drug $\times$ dose group $\times$ order, $p = 0.975$; time $\times$ order, $p = 0.248$; time $\times$ dose group $\times$ order, $p = 0.519$; reward $\times$ dose $\times$ group $\times$ order, $p = 0.962$; drug $\times$ time $\times$ order, $p = 0.270$; drug $\times$ time $\times$ dose group $\times$ order, $p = 0.709$; drug $\times$ reward $\times$ order, $p = 0.723$; drug $\times$ reward $\times$ dose group $\times$ order, $p = 0.438$; drug $\times$ time $\times$ reward $\times$ order, $p = 0.642$; drug $\times$ time $\times$ reward $\times$ dose group $\times$ order, $p = 0.585$). As a follow up, to determine whether an order effect interacted with our key observation (that L-DOPA modulated corrected remember hits for neutral items), we performed a *post hoc* ANOVA for these responses only. This also showed no interac-

Table 4. Regression analyses between remember and know responses and weight-adjusted dose of L-DOPA

There was a significant quadratic relationship between dose and early and delayed remember responses for neutral items. A linear relationship was also seen for early remember responses for neutral items. * $p < 0.05$.

Figure 2. Delayed test results for recollection of neutral items. *a*, Significant quadratic correlation (indicated by the dashed inverted U-shaped line) between the weight-adjusted dose of L-DOPA and corrected remember hits for neutral items at delayed test. *b*, Corrected remember hits on L-DOPA minus placebo for participants divided into three groups based on the amount of L-DOPA they received. Performance was significantly different between all three groups, and better recollection on L-DOPA than placebo (indicated by performance above the dashed line) was seen for participants receiving the middle dose (average of 2 mg/kg). Bars represent mean $\pm$ 1 SEM. * $p < 0.05$, two tailed.

Figure 3. Difference between L-DOPA and placebo remember hits and false alarms for neutral items at delayed test. The behavioral enhancement of memory by L-DOPA compared with placebo in the middle-dose group was attributable to an increase in remember hits with no change in false alarms. Bars represent mean $\pm$ 1 SEM. * $p < 0.05$.

tions with drug order (drug $\times$ time of test $\times$ dose group $\times$ order, $F = 1.121$, $p = 0.343$), confirming that order effects were not present.

Subsequent memory effects on fMRI data

To analyze subsequent memory effects of the fMRI data acquired during encoding, we contrasted activation for items at encoding that were subsequently recognized (both remember and know responses) with items that were subsequently forgotten (classified as new during test). We collapsed over early and delayed tests and excluded participants with $< 10\%$ of trials in a category of interest to ensure that analyses were statistically robust (when participants are excluded, we report the number of subjects for that particular analysis). The contrast “remember and

know $>$ forget” revealed subsequent memory activation in the left parahippocampal gyrus [MNI space coordinates (x, y, z), $-30, -38, -14$; peak $Z = 5.02$; $p < 0.05$ whole-brain FWE] and left mid-occipital gyrus (MNI coordinates, $-44, -72, 26$; peak $Z = 5.27$; $p < 0.05$ whole-brain FWE) (Fig. 4*a*). This contrast did not reveal activation in the hippocampus or SN/VTA, nor was activity seen in these regions when examining for an interaction between memory and pharmacological manipulation (results at the uncorrected threshold, $p < 0.001$, are available on request).

The behavioral effect we demonstrated of L-DOPA on episodic memory (indexed by remember responses) was restricted to neutral items. This motivated an additional analysis to identify areas of activation that showed a subsequent memory effect for recollection of neutral items alone ($n = 23$ participants that fulfilled the 10% correct criteria described above). This revealed activation in a cluster extending into the left hippocampus (MNI coordinates, $-26, -33, -11$; peak $Z = 4.01$; $p < 0.05$ FWE SVC for bilateral hippocampus ROI) (Fig. 5*a*; for all uncorrected results, see Table 5). Here there was no main effect of drug using a functional ROI approach ($F_{(1,22)} = 1.952$, $p = 0.176$) (Fig. 5*b*). For this contrast, we found an interaction between memory (remember $>$ forget) and drug (L-DOPA $>$ placebo) in the SN/VTA (MNI coordinates, $5, -18, -18$; peak $Z = 4.15$; $p < 0.01$ FWE SVC for bilateral SN/VTA ROI), whereby greater activation for forgotten compared with remembered neutral scenes on placebo was reversed by L-DOPA (for full uncorrected results, see Table 6). Another cluster with a peak in the right ventricle (MNI coor-

Figure 4. Medial temporal lobe activation for subsequent memory. **a**, Difference in activation for subsequently recognized (remember and know) versus forgotten items in the left parahippocampal gyrus ($n = 29$). **b**, Activation in both left and right hippocampi, extending into parahippocampal gyri for remembered versus forgotten items ($n = 23$). Displayed at the level of peak activation in the left hippocampus (circled). Images displayed at the uncorrected threshold $p < 0.001$ on a group-averaged MT image.

ordinates, 20, -37 , 9; peak $Z = 5.07$; $p < 0.05$ whole-brain FWE; 214 voxels), of which only a small part extended into the right hippocampus (MNI coordinates, 18, -36 , 7; peak $Z = 4.01$; $p < 0.05$ FWE SVC for bilateral hippocampus ROI; 16 voxels) will not be considered further. We did not find any regions of activation for the interaction between memory and placebo $>$ L-DOPA.

Dose-dependent modulation of encoding activity

Given the dose-dependent nonlinear effect of L-DOPA on episodic memory performance for neutral events, we extracted parameter estimates from the functional hippocampal cluster for subsequent memory (remember-minus-forgotten responses for neutral events) on L-DOPA and used this measure in a regression analysis with the weight-adjusted dose of L-DOPA as the independent variable (as used for the behavioral regression analyses).

We found that L-DOPA modulated hippocampal activation for subsequent episodic memory for neutral items in a nonlinear U-shaped pattern (regression with L-DOPA dose for $n = 21$; quadratic: $F_{(2,18)} = 7.68$, $p = 0.004$, $R^2 = 0.46$; linear regression: $F_{(1,19)} = 2.27$, $p = 0.152$, $R^2 = 0.11$) (Fig. 5c). Next, we explored how these parameter estimates related to the previously denoted weight-adjusted dose groups, in which we previously identified behavioral enhancement of memory by L-DOPA in those who received the middle dose. Within this cohort of 21 subjects, six participants were from the low-dose group, eight from the middle-dose group, and seven from the high-dose group. Hippocampal parameter estimates significantly differed between the three groups (one-way between-group ANOVA: $F_{(2,20)} = 8.767$, $p = 0.002$; mean difference between low- and middle-dose groups = 4.32, $p = 0.003$; mean difference between low- and

high-dose groups = 3.77, $p = 0.01$). Figure 5d illustrates that, although the low-dose group showed what could be considered a “standard” pattern of activation (more activity for subsequently remembered than forgotten items), both the middle- and high-dose groups showed no difference in encoding-related activity. Thus, we show a dose-dependent reduction of the subsequent memory effect by L-DOPA, evident in participants whose memory improved on L-DOPA (i.e., the middle-dose group).

We found activation in both the left hippocampus (MNI coordinates, -29 , -34 , -6 ; peak $Z = 4.38$; $p < 0.05$ FWE SVC) and right hippocampus (MNI coordinates, 29, -33 , -11 ; peak $Z = 4.27$; $p < 0.05$ FWE SVC) for items remembered more than forgotten when collapsing across both rewarded and neutral items (Fig. 4b; uncorrected results available on request). However, these parameter estimates ($n = 21$) were not robustly modulated by the weight-adjusted dose of L-DOPA (left hippocampus: quadratic model, $F = 3.01$, $p = 0.074$; linear model, $F = 1.79$, $p = 0.197$; right hippocampus: quadratic model, $F = 0.071$, $p = 0.932$; linear model, $F = 0.071$, $p = 0.793$), which, in keeping with our behavioral results, indicated a high degree of specificity of our neural findings for neutral items.

Discussion

We show that, in healthy older adults, dopamine enhances recollection of neutral scenes in a dose-dependent inverted U-shaped pattern, in which a dose of ~ 2 mg/kg body weight improved recollection in contrast to higher and lower doses, which were ineffective. This pattern was not explained by encoding-related activity in the hippocampus, supporting a view that dopamine modulates a post-encoding consolidation process. In fact, our

Figure 5. Dose-dependent U-shaped modulation of hippocampal activity by L-DOPA. Left hippocampal activity for neutral items that were remembered compared with those that were forgotten (**a**, **b**). **c**, Parameter estimates from this left hippocampal region ($n = 21$) for remembered-minus-forgotten items showed a nonlinear (U-shaped) modulation by the weight-adjusted dose of L-DOPA (dashed line), where values around zero indicate no difference in encoding-related activity for subsequently remembered and forgotten items. Thus, hippocampal activity at encoding did not predict the improvement in recollection seen in participants receiving the middle dose of L-DOPA (**d**). Bars represent mean $\pm$ 1 SEM. $*p < 0.05$.

data fit neatly with an influential model of molecular consolidation in the hippocampus, in which encoding only leads to a short-lasting strengthening of synaptic connections. Dopamine-dependent protein synthesis is then necessary to stabilize and maintain these connections (Lisman et al., 2011). Our behavioral data align with these findings in our demonstration that L-DOPA, compared with pla-

cebo, affects primarily delayed, but not early, recollection performance.

Our neuroimaging data reveal whether the benefits of L-DOPA can be attributed to an enhancement in the hippocampal contribution to encoding. Molecular consolidation invokes effects on long-term plasticity as evident in animal models of

long-term potentiation (Frey and Morris, 1997; Smith et al., 2005; Bethus et al., 2010). There is behavioral evidence in rodents that dopamine antagonists at encoding do not impair hippocampus-dependent memories tested after short delays but do cause an impairment after long delays (Bethus et al., 2010). According to the “synaptic-tagging and capture model,” the benefit of dopamine arises out of an effect on protein synthesis linked to consolidation (Frey and Morris, 1997; Morris et al., 2003). In fact, this post-encoding benefit of dopamine predicts that items that engender low levels of hippocampal activation at encoding, which may be classed as know or forgotten, should be “rescued” by subsequent protein synthesis. This ability to later remember also weakly encoded events should lead to a decrease of encoding-related hippocampal subsequent memory activation under L-DOPA. Our data show this to be the case highlighting is a tight dose–response relationship between L-DOPA dose, behavior, and fMRI effects. An fMRI subsequent memory effect in the hippocampus was modulated in a dose-dependent nonlinear U-shaped manner, whereby it was entirely abolished under an optimal dose of L-DOPA. Note that the combination of behavioral assessment after long retention intervals and fMRI data from the time of encoding is a key strength of our study, allowing, for the first time in humans, identification of a post-encoding mechanism that accounts for improved memory recollection after L-DOPA.

Evidence from molecular imaging studies using PET link dopamine receptor density to cognitive performance, whereby dopamine binding in the striatum and hippocampus correlate with

standard neuropsychological measures of immediate recall (Takahashi et al., 2007; Cervenka et al., 2008). Importantly, dopamine loss with age of both D₂ receptors and dopamine transporter mediate age-related episodic memory deficits (Bäckman et al., 2000; Erixon-Lindroth et al., 2005). Such studies have used immediate recall as a measure of episodic memory, which suggests that dopamine can modulate encoding processes. Our study expands on this empirical molecular imaging evidence by using a functional measure of encoding in relation to subsequent memory tested after long retention intervals to infer dopaminergic modulation of post-encoding consolidation processes.

An inverted U-shaped effect of dopamine on working memory performance, which is dependent on dopamine effects within the prefrontal cortex, is well recognized (Williams and Goldman-Rakic, 1995; Goldman-Rakic et al., 2000; Cools et al., 2001). In this model, an optimal dose of dopamine enhances function, but higher doses are detrimental. Our results show the same effect of dopamine on episodic memory performance, as well as a dose-dependent modulation of hippocampal activity. We suggest that the memory improvement from the optimal dose of L-DOPA results from increased hippocampal protein synthesis. Although higher doses of dopamine may increase protein synthesis in the hippocampus, other mechanisms are likely to account for a lack of improvement in recollection. At a molecular level, excess dopamine can induce a long-term depression through inhibition of NMDA receptors, thereby inhibiting memory consolidation (Thirugnanasambandam et al., 2011). At a systems level, a model that explains the physiology underlying the inverted U-shaped

phenomenon in working memory invokes moderate amounts of dopamine enhancing excitatory inputs to pyramidal cells, with higher levels associated with greater interneuron activity leading to inhibition of pyramidal cells and thus impaired cognitive performance (Goldman-Rakic et al., 2000). It should be noted that our fMRI data rule out an enhanced excitatory input to pyramidal cells as the mode of action through which dopamine boosted late memory under optimal doses. Such a mechanism would have been associated with increased hippocampal activation for subsequently recollected events under the optimal dose of L-DOPA. Finally, although we report the subsequent memory effects of L-DOPA in the SN/VTA for completeness, we did not entertain any specific hypothesis regarding the direction of effect of L-DOPA for this contrast because of the potential complexity of the effect dopamine exerts in this region (for example, the effect of D_2 autoreceptors on the firing rate of neurons as a consequence of manipulating the availability of dopamine). To determine whether there is an optimal dose of L-DOPA for boosting the long-term persistence of episodic memories, future studies could combine our paradigm with a wide range of different dosages coupled with a measure of underlying dopamine reserve using molecular imaging methods (e.g., PET).

The dose-dependent effects of L-DOPA on both recollection and hippocampal activity were restricted to neutral items. SN/VTA activation in response to novelty has been demonstrated previously (Bunzeck and Düzel, 2006), suggesting that dopamine neurons are responsive to novelty even in the absence of apparent reward (Krebs et al., 2009, 2011; Düzel et al., 2010). We anticipated L-DOPA would improve memory recollection for neutral items because a novelty induced dopamine release in response to these items would be expected. This is indeed what we found.

It is a well established observation that dopamine release is increased by reward prediction (Schultz et al., 1997). This effect of reward has been associated with improved long-term memory in younger adults, in which recollection was better for reward-predicting compared with neutral items when tested after a delay of 3 weeks (Wittmann et al., 2005). We included a reward component in our task as a way of manipulating endogenous dopamine release, so as to compare its effect with the exogenous manipulation through administration of L-DOPA. Our hypothesis was that reward would shift the dose–response relationship between memory performance at the delayed test and L-DOPA to the left. However, we found no effect of reward on recollection at delayed test or any interaction with L-DOPA. One possible reason for this is that reward prediction in our task failed to elicit increased phasic dopamine release. Impaired reward processing, particularly in tasks with probabilistic reward, has been reported with increasing age (Marschner et al., 2005; Schott et al., 2007; Mell et al., 2009; Eppinger et al., 2011), and therefore the effects of reward-predicting cues in our task, both alone and in combination with L-DOPA, may have been more variable. We speculate that an interesting implication of our data is that L-DOPA administration in older adults does not reconstitute the known effects of reward anticipation, i.e., even under L-DOPA, there is no benefit of reward on memory, suggesting that a lack of dopamine cannot account for the lack of a reward-related memory enhancement of memory in old age.

We took advantage of the inter-individual variation in body weight to determine relative dose-dependent effects of L-DOPA, because the effective dose of L-DOPA is dependent on body weight (Zappia et al., 2002). The enhancement of memory in the middle-dose group at delayed test on L-DOPA compared with placebo suggests that memory performance differences were at-

tributable to the drug rather than body weight or other variables associated with body weight. Furthermore, health-related measures and general cognitive performance did not differ between the three body weight dose groups and therefore were unlikely to account for differences in memory performance. However, we acknowledge a limitation of this study is that other unmeasured variables associated with body weight may have influenced memory performance across participants (Volkow et al., 2012).

Because dopamine loss varies across older individuals, we cannot be certain that all participants responded to L-DOPA in a similar manner. Although we did not have a true measure of intrinsic dopamine signaling, we obtained MT values of the SN/VTA. This demonstrated inter-individual variability in the structural integrity of dopaminergic midbrain but, importantly, did not relate to differences in memory performance or body weight. Thus, MT is one measure that illustrates that, although there was variable integrity of the dopaminergic midbrain among our cohort of older adults, this did not modulate memory performance or interact with L-DOPA. Hence, we do not have a strong reason to believe that our participants showed markedly different physiological responses to L-DOPA. Molecular imaging methods such as PET would be required to characterize body-weight-related responsiveness to L-DOPA more fully.

The possibility of selectively influencing consolidation in humans, whilst not affecting encoding, has remained primarily theoretical (with the exception of sleep-related studies), and, to the best of our knowledge, our study is the first demonstration of this in conjunction with a measure of encoding activity. By combining behavioral and fMRI data with a pharmacological manipulation, we have identified a specific effect of dopamine on consolidation rather than encoding and could characterize its narrow dose range. The research we report has wider implications given that an episodic memory decline with increasing age is both common and distressing. Thus far, research into post-encoding consolidation processes in old age has been primarily neglected. Our findings indicate that this may be an important area for research because, by enhancing post-encoding consolidation, memory for weakly encoded events can be rescued. Hence, an exogenous modification of consolidation can potentially compensate for hippocampal deficits in encoding, thereby providing a new therapeutic perspective to memory dysfunction.
