Astrocytes are found throughout the brain where they make extensive contacts with neurons and synapses. Astrocytes are known to display intracellular Ca^{2+} signals and release signaling molecules such as D-serine into the extracellular space. However, the role(s) of astrocyte Ca^{2+} signals in hippocampal long-term potentiation (LTP), a form of synaptic plasticity involved in learning and memory, remains unclear. Here, we explored a recently discovered novel TRPA1 channel-mediated transmembrane Ca^{2+} flux pathway in astrocytes. Specifically, we determined whether block or genetic deletion of TRPA1 channels affected LTP of Schaffer collateral to CA1 pyramidal neuron synapses. Using pharmacology, *TRPA1*^{−/−} mice, imaging, electrophysiology, and D-serine biosensors, our data indicate that astrocyte TRPA1 channels contribute to basal Ca^{2+} levels and are required for constitutive D-serine release into the extracellular space, which contributes to NMDA receptor-dependent LTP. The findings have broad relevance for the study of astrocyte–neuron interactions by demonstrating how TRPA1 channel-mediated fluxes contribute to astrocyte basal Ca^{2+} levels and neuronal function via constitutive D-serine release.

Introduction

Astrocytes are found throughout the brain and their close proximity and contact with neurons has been known for over a century (DeFelipe, 2010). More recent anatomical studies show that single astrocytes have nonoverlapping territories encompassing thousands of synapses (Bushong et al., 2002; Halassa et al., 2007), and electron microscopy shows that 57% of all excitatory synapses in the stratum radiatum region of the hippocampus are adjacent to astrocyte processes (Ventura and Harris, 1999). Thus, astrocytes are an important part of neuronal networks, where they serve homeostatic roles, contribute to synapse formation, respond to neuronal excitation, and regulate neuronal function (Barres, 2008; Halassa and Haydon, 2010). However, our understanding is still incomplete and several fundamental questions remain open, including if/how astrocyte Ca^{2+} signals contribute to synaptic plasticity.

Pioneering studies showed that astrocytes synthesize, contain, and release D-serine (Hashimoto et al., 1993; Schell et al., 1995, 1997; Wolosker et al., 1999; Mothet et al., 2000). Later, D-serine was shown to be required for LTP because of its coagonist actions at the “glycine site” of NMDA receptors (NMDAR; Yang et al., 2003). Subsequent studies also showed that astrocyte-derived D-serine regulated LTP within the hippocampus *in situ* (Basu et al., 2009; Henneberger et al., 2010) by selectively targeting synaptic NMDARs (Papouin et al., 2012) and that a D-serine-dependent form of cortical plasticity occurred *in vivo* (Takata et al., 2011). Of note, three studies highlighted the potential importance of hippocampal astrocyte Ca^{2+} signaling in regulating D-serine release and long-term potentiation (LTP; Mothet et al., 2000; Henneberger et al., 2010; Kang et al., 2013). In contrast, a separate study demonstrated that the deletion of IP3 type 2 receptors (IP3R2) abolished Ca^{2+} elevations mediated by intracellular stores, but had no effect on hippocampal LTP (Agulhon et al., 2010). At first sight, these studies seem contradictory (Kirchhoff, 2010), but perhaps a deliberated interpretation is warranted, because abolishing store-mediated Ca^{2+} release is not the same physiologically or biophysically as chelating Ca^{2+} with organic Ca^{2+} buffers, especially since astrocytes contain multiple Ca^{2+} sources (Nedergaard and Verkhratsky, 2012). From this perspective the recent discovery of TRPA1 channels as mediating a transmembrane Ca^{2+} flux pathway that (1) is independent of intracellular stores and (2) contributes to free basal Ca^{2+} levels in stratum radiatum region astrocytes (Shigetomi et al., 2012) provided a unique opportunity to explore if this novel pathway contributes to LTP (for review, see Clarke and Attwell, 2012; Tong et al., 2013; Scimemi, 2013). Recently these studies have been extended to show that hippocampal astrocytes display TRPA1 responses and express TRPA1 mRNAs (Nagai et al., 2004; Kimura

et al., 2013). Moreover, TRPA1 proteins have been localized to astrocyte processes by immunogold electron microscopy (Lee et al., 2012). Thus, the possible role(s) of TRPA1 channels in LTP is an important issue to address, because stratum radiatum region astrocytes express TRPA1 channels, and also have the highest content of D-serine in relation to other regions of the brain (Schell et al., 1995, 1997). Additionally, the mechanisms that regulate D-serine release from astrocytes are not fully explored or completely understood (Oliet and Mothet, 2006, 2009).

Materials and Methods

Wild-type and mutant mice. Homozygous *TRPA1*^{−/−} mice (Kwan et al., 2006; Shigetomi et al., 2012) backcrossed onto a C57BL/6J background were a gift from Dr. David P. Corey (Harvard Medical School, Boston, MA). The backcrossed *TRPA1*^{−/−} mice were maintained as homozygotes: control mice for comparisons were C57BL/6J. Heterozygous *IP3R2*^{−/−} mice (Li et al., 2005) were a gift from Dr. Ju Chen (University of California San Diego, La Jolla, CA). The *IP3R2*^{−/−} mice were maintained as heterozygotes. Homozygotes and their wild-type (WT) littermates were used.

Reverse transcription PCR analysis of TRPA1 transcripts in purified astrocyte cultures. Purified astrocytes were prepared as previously described in detail (Shigetomi and Khakh, 2009; Shigetomi et al., 2010, 2012). Total RNAs were extracted from cultured astrocytes using the RNeasy Mini kit (Qiagen) with QIAshredder (Qiagen) according to the manufacturer's protocols. Reverse transcription (RT) was performed at 40°C for 60 min in a reaction volume of 25 μ l containing 500 ng of total RNAs, 5 $\times$ First-Strand Buffer (Invitrogen), 0.5 μ g oligo (dT) (Invitrogen), 200 μ M dNTP mix (Ambion), nuclease free water (Ambion), and 200 U M-MLV Reverse Transcriptase (Invitrogen). PCR amplification was performed in a reaction volume of 50 μ l containing 10 $\times$ PCR buffer, 5 $\times$ Q solution, 250 μ M dNTPs, 1 μ M each of forward and reverse primers, and 2.5 U TaqDNA polymerase (Qiagen). PCR amplification included denaturation at 95°C for 5 min, 35 cycles at 95°C for 60 s, 50°C (for TRPA1) or 56°C (for glial fibrillary acidic protein; GFAP) for 45 s, and 72°C for 60 s, followed by 72°C for 10 min. Primers used were as follows: TRPA1 (5'-GATCTTCGTGTTGCCCTTATTC-3' and 5'-ATAAACACTCCCGTCGATCTC-3') and GFAP (5'-AGAAAC CAGCCTGGACACCAAA-3' and 5'-TGGGAATTGGGCCTAGCAAA CA-3'). Following the PCR, 20 μ l samples of PCR product were analyzed by agarose gel electrophoresis. The controls were processed identically but lacked reverse transcriptase (these gave no detectable bands on the gels; see Fig. 1).

Field EPSP recordings and induction of LTP. Standard techniques were used as described by us (Carlisle et al., 2008; Moody et al., 2011) to prepare 400 μ m hippocampal slices from halothane- or isoflurane-anesthetized 8- to 18-week-old mice. Slices were maintained in interface type chambers (Fine Science Tools) at 30°C in oxygenated (95% O₂/5% CO₂) artificial CSF (ACSF) containing the following (in mM): 124 NaCl, 4.4 KCl, 25 NaHCO₃, 1 NaH₂PO₄, 2 CaCl₂, 1.2 MgSO₄, and 10 glucose (flow rate = 2–3 ml/min). A bipolar nichrome wire stimulating electrode was placed in stratum radiatum of the hippocampal CA1 region to activate Schaffer collateral fiber synapses onto CA1 pyramidal cells and the resulting field EPSPs (fEPSPs) were recorded using an extracellular glass microelectrode (filled with ACSF; resistance = 5–10 M Ω) placed in stratum radiatum. Presynaptic fibers were stimulated once every 50 s using a stimulation intensity (5–11 V, 20 μ s) that evoked approximately half-maximal fEPSPs. LTP was induced using two 1 s trains of 100 Hz stimulation (intertrain interval = 10 s).

Brain slice whole-cell voltage-clamp recordings. The methods used have been described previously (Carlisle et al., 2008; Moody et al., 2011). Briefly, slices with CA3 region removed were maintained in a submerged slice recording chamber and bathed in a modified ACSF containing picrotoxin (100 μ M), elevated concentrations of CaCl₂ and MgSO₄ (4 mM each), and a lower concentration of KCl (2.4 mM). Whole-cell patch-clamp recordings were performed with intracellular solution comprising the following (in mM): 102 Cs gluconate, 10 K gluconate, 20 CsCl, 0.1 EGTA, 20 HEPES, 10 TEA-Cl, 5 QX-314, 4 Mg-ATP, and 0.3 Tris-GTP,

pH 7.2, osmolarity 295 mOsm. The resistance of the pipettes was 4–6 M Ω . Membrane currents were recorded using pCLAMP 9 software, Axopatch1D amplifier, and Digidata 1322A (Molecular Devices). To examine the AMPA receptor (AMPA)- and NMDAR-mediated components of the evoked EPSCs, we measured the amplitude of EPSCs recorded at postsynaptic membrane potentials of −80 or +40 mV. The AMPAR-mediated component of the EPSC was measured at the time after EPSC onset corresponding to the peak amplitude of the EPSC at −80 mV (~3–5 ms), while the amplitude of the EPSC 50 ms after onset was used to estimate the NMDAR-mediated component.

Surgery and in vivo microinjections of adeno-associated virus 2/5. Adeno-associated viruses (AAVs) of the 2/5 serotype, using the minimal gfaABC₁D promoter and capable of expressing the membrane-targeted genetically encoded calcium indicator (GECI) Lck-GCaMP3 specifically within astrocytes, were available from recent studies (Shigetomi et al., 2013). Then 7- to 8-week-old male and female C57BL/6 mice were used in all experiments in accordance with institutional guidelines. All surgical procedures were conducted under general anesthesia using continuous isoflurane (induction at 5%, maintenance at 1–2.5% v/v). Depth of anesthesia was monitored continuously and adjusted when necessary. Following induction of anesthesia, the mice were fitted into a stereotaxic frame with their heads secured by blunt ear bars and their noses placed into an anesthesia and ventilation system (David Kopf Instruments). Mice were administered 0.05 ml of buprenorphine (Buprenex; 0.1 mg/ml) subcutaneously before surgery. The surgical incision site was then cleaned three times with 10% povidone iodine and 70% ethanol. Skin incisions were made, followed by craniotomies of 2–3 mm in diameter above the left parietal cortex using a small steel burr (Fine Science Tools) powered by a high-speed drill (K.1070; Foredom). Saline (0.9%) was applied onto the skull to reduce heating caused by drilling. Unilateral viral injections were performed by using a stereotaxic apparatus (David Kopf Instruments) to guide the placement of beveled glass pipettes (1B100–4; World Precision Instruments) into the left hippocampus (2 mm posterior to bregma, 1.5 mm lateral to midline, and 1.6 mm from the pial surface). Two microliters of AAV2/5 gfaABC₁D Lck-GCaMP3 (1.2 $\times$ 10¹³ gc/ml) was injected by using a syringe pump (Pump11 Pico-Plus Elite; Harvard Apparatus). Glass pipettes were left in place for at least 10 min. Surgical wounds were closed with single external 5–0 nylon sutures. Following surgery, animals were allowed to recover overnight in cages placed partially on a low-voltage heating pad. Buprenorphine was administered two times per day for up to 2 d after surgery. In addition, trimethoprim sulfamethoxazole (40 and 200 mg, respectively, per 500 ml water) was dispensed in the drinking water for 1 week. Mice were killed 12–20 d postsurgery for imaging (typically 13–15 d). Based on our past experience (Shigetomi et al., 2013), we chose this period since generally it takes ~2 weeks to achieve GECI expression in cells by AAV infection and because it has been suggested that long-term expression (>3 weeks post-AAV injection) can cause toxicity in neurons (Akerboom et al., 2012).

Brain slice astrocyte Ca²⁺ imaging using Fluo-4. Coronal slices of hippocampus (300 μ m) of 9- to 11-week-old C57BL/6J mice or *TRPA1*^{−/−} mice were cut in solution comprising (in mM): 87 NaCl, 25 NaHCO₃, 2.5 KCl, 1.25 NaH₂PO₄, 25 D-glucose, 75 sucrose, 7 MgCl₂, and 0.5 CaCl₂ saturated with 95% O₂ and 5% CO₂. Slices were incubated at ~34°C for 30 min and subsequently stored at room temperature in ACSF comprising (in mM): 126 NaCl, 2.5 KCl, 1.3 MgCl₂, 10 D-glucose, 2.4 CaCl₂, 1.24 NaH₂PO₄, and 26 NaHCO₃ saturated with 95% O₂ and 5% CO₂. Brain slices were loaded at room temperature in the dark with 5 μ M Fluo-4/AM (Invitrogen) in ACSF for 60 min, then transferred to dye-free ACSF for at least 30 min before experimentation to allow for cleavage of the AM ester group. Live astrocytes were predominantly loaded with the fluorescent dye with these conditions. This was confirmed by simultaneous acquisition of infrared-differential interference contrast images of astrocytes in the same area. Slices were imaged using an Olympus Fluoview 300 laser-scanning confocal microscope with a 20 mW argon laser, at <2% power. Emitted green fluorescence was collected through a 515 long-pass filter. Fluoview software was used for image acquisition. Imaging was performed in the presence of 6-cyano-2,3-dihydroxy-7-nitroquinoxaline (10 μ M), DL-(−)-2-amino-5-phosphono-pentanoic acid (20 μ M), bicuculline (10 μ M), and tetrodotoxin (1 μ M). We added the same concentra-

tion of 0.1% dimethylsulfoxide in the control buffer, when we applied HC 030031.

D-Serine biosensor measurements. D-Serine and null biosensor electrodes, 0.5 mm in length and 50 μ m in diameter, were purchased from Sarissa Biomedical and used following the manufacturer's instructions (Dale et al., 2005). The biosensor electrodes were mounted on Narishige micromanipulators to allow for manual positioning within hippocampal slices, which were maintained exactly as described above. Changes in electrical potential of the biosensors were measured using a Potentiostat Model 3104 (Pinnacle Technology). Biosensors and null sensors were rehydrated in ACSF before use for $\sim$ 1 h and allowed to polarize to +500 mV over 30 min. Biosensors and null reference sensors were rapidly advanced into the stratum radiatum of CA1. D-Serine biosensor currents were measured by subtracting the current recorded from the reference null biosensor (which lacks D-amino acid oxidase; see Fig. 7A) from the D-serine biosensor. We only analyzed steady-state D-serine levels within slices, and did not measure the decay of the [D-serine] upon impaling the slices (see Results; Fig. 7C,D). In this regard, our use of the D-serine biosensors to measure steady-state in-slice ambient D-serine concentrations is similar to recent work that measured in-slice adenosine levels (Schmitt et al., 2012). Sensors were calibrated before and after every experiment with 10 μ M D-serine to measure the sensitivity of the biosensors, and 10 μ M 5-HT to check for reaction to nonspecific electro-active compounds. Current changes during the different experimental conditions were compared with the post experiment calibration with the standards. The biosensors were extremely sensitive to, and selective for, D-serine, and responded in a linear manner to varying concentrations of the compound (Fig. 7B).

Data analysis. Data were analyzed using pCLAMP10 (Molecular Devices), Origin 8 (OriginLab), ImageJ (National Institutes of Health, Bethesda, MD), and GraphPad InStat 3.06 (GraphPad Software). All statistical tests were run in Origin 8 or GraphPad InStat 3.06 using paired or unpaired Student's *t* tests as appropriate, with significance declared at $p < 0.05$, which was indicated by one star in the figures. Significant differences with $p < 0.01$ were indicated with two stars in the figures. Origin 8 was also used for creating graphs. Data are as mean $\pm$ SEM from *n* experiments as indicated in the text (where *n* is the number of slices for fEPSP and biosensor experiments and the number of cells for patch-clamp experiments, as indicated in each of the figures) from between three and eight mice.

Chemicals. All reagents were from VWR, Invitrogen, Sigma-Aldrich, or Ascent Scientific.

Results

Initial observations on the expression of TRPA1 in astrocytes

In our recent studies, we provided evidence for the expression of functional TRPA1 channels in hippocampal astrocytes based on imaging, patch-clamp electrophysiology, siRNA knock-down, knock-out mice, pharmacological screening, TRPA1 selective antagonists, astrocyte-enriched cultures, and Western blot analysis (Shigetomi et al., 2012). This work has now been reviewed and discussed in detail by us and others (Clarke and Attwell, 2012; Tong et al., 2013; Scimemi, 2013). However, we did not perform transcript analysis in the past work and thus began the present study by using RT-PCR to seek to identify TRPA1 transcripts in hippocampal astrocyte enriched cultures. The data shown in Figure 1 show that TRPA1 transcripts were detected in hippocampal astrocytes by RT-PCR, at lower levels than GFAP controls ($p < 0.01$ unpaired Student's *t* test; $n = 3$). Moreover, no transcripts were detected for either TRPA1 or GFAP in samples identically prepared but lacking in reverse transcriptase (Fig. 1). Overall, our RT-PCR data are consistent with recent TRPA1 RT-PCR data for hippocampal astrocytes (Kimura et al., 2013). Together with past work from us (Shigetomi et al., 2012) and others (Kimura et al., 2013) showing functional TRPA1 and TRPA1 protein expression within astrocytes, and with recent immunogold electron microscopy studies showing that TRPA1 channels are localized to astro-

Figure 1. RT-PCR evidence for TRPA1 mRNAs in hippocampal astrocytes. The gel shows the results of RT-PCR experiments for TRPA1 and GFAP (control) with and without reverse transcriptase for mRNA harvested from purified hippocampal astrocytes. The lower bar graph quantifies the results from multiple experiments ($n = 3$).

cyte peripheral processes (Lee et al., 2012), our data show that hippocampal astrocytes also express TRPA1 transcripts (Fig. 1).

We recall that a published gene chip transcriptome database did not find that TRPA1 mRNAs were enriched in astrocytes relative to other cells such as neurons (Cahoy et al., 2008). However, it is important to note that this study only analyzed mRNAs in a population of S100 β -positive astrocytes from entire forebrain (Cahoy et al., 2008). In contrast, the TRPA1 RT-PCR work reported here (Fig. 1) and in published work (Kimura et al., 2013) specifically analyzed all hippocampal astrocytes irrespectively of whether they expressed S100 β or not. This is relevant because of the growing realization that astrocytes represent a genetically and functionally heterogeneous group of cells (Zhang and Barres, 2010; Oberheim et al., 2012).

TRPA1 channels mediate a proportion of microdomain Ca^{2+} signals in astrocytes

Astrocyte TRPA1 channel-mediated spotty microdomain Ca^{2+} signals have been observed using evanescent wave microscopy and membrane-tethered genetically encoded calcium indicators in cultured astrocytes (Shigetomi et al., 2010, 2012). By "spotty," we mean that the signals were localized to microdomains and occurred randomly without any external stimulation. These studies showed that localized microdomain Ca^{2+} entry via TRPA1 channels dissipated and thus contributed significantly to basal Ca^{2+} at $\sim$ 120 nM in cultures and *in situ* within brain slices of young rodents (Shigetomi et al., 2012). Conversely, blocking TRPA1 reduced basal Ca^{2+} to $\sim$ 60 nM. Moreover, within the CA1 region of the hippocampus, functional TRPA1 channels were only detected in astrocytes and not within neurons (Shigetomi et al., 2012). With these studies as a basis, we next determined whether TRPA1 channels contributed to (1) microdomain Ca^{2+} signals and (2) basal Ca^{2+} levels of astrocytes in hippocampal slices from adult mice.

TRPA1 channel-mediated microdomain Ca^{2+} signals cannot be reliably monitored with cytosolic Ca^{2+} indicator dyes, because these dyes do not enter fine branches and branchlets and/or because the underlying signals are small and most pronounced in near plasma membrane regions (Shigetomi et al., 2010, 2012). However, we showed that TRPA1-mediated signals can be observed using plasma membrane-targeted GECIs (Shigetomi et al.,

2010, 2012). To explore contributions of TRPA1 channels to microdomain Ca^{2+} signals in astrocytes *in situ* from adult mice, we used AAVs specifically developed to study near membrane Ca^{2+} signals in entire astrocytes (Shigetomi et al., 2013). As recently reported during the development and characterization of Lck-GCaMP3 viruses (Shigetomi et al., 2013), using this approach we measured numerous Ca^{2+} signals in astrocyte branches. We used the selective TRPA1 blocker HC 030031 (McNamara et al., 2007; Eid et al., 2008) to determine whether any of these were due to TRPA1. As can be seen in the representative traces shown in Figure 2, A and B, HC 030031 reduced the numbers of microdomain Ca^{2+} signals observed in astrocytes. To quantify this result, we analyzed the amplitude (dF/F), half-time ($T_{0.5}$), and frequency of the microdomain Ca^{2+} signals before and during HC 030031 applications ($80 \mu\text{M}$). We found that HC 030031 significantly reduced the amplitude and frequency of microdomain Ca^{2+} signals by $\sim 20\%$ (Fig. 2C; $n = 12$ cells; $p < 0.05$ by paired Student's *t* tests). Thus the peak event dF/F in control and in the presence of HC 030031 was 1.3 ± 0.03 and 1.1 ± 0.02 , respectively ($n = 944$ and 598 events, $p < 0.01$ with a paired Student's *t* test). The event frequency for control and in the presence of HC 030031 was 1.4 ± 0.07 and 1.0 ± 0.06 events/min ($n = 139$ and 120 sites, $p < 0.01$ with a paired Student's *t* test). However, HC 030031 produced no change in the $T_{0.5}$ of the events (3.6 ± 0.12 and 3.6 ± 0.1 s for control and in the presence of HC 030031, $n = 944$ and 598 events). Further analysis showed that HC 030031 reduced the total number of Ca^{2+} events measured per cell ($n = 12$ astrocytes; Fig. 2D), but that this reduction occurred over entire astrocytes and not at a specific distance from the soma (Fig. 2E). This latter result suggests that TRPA1 channels are diffusely expressed throughout astrocyte branches, which is consistent with the uniform distribution of astrocyte branchlets as determined by light and electron microscopy (Shigetomi et al., 2013) and with recent immunogold electron microscopy studies showing TRPA1 in astrocyte processes (Lee et al., 2012). Overall, these data suggest that $\sim 20\%$ of the spontaneous Ca^{2+} signals seen within entire astrocytes using Lck-GCaMP3 are due to TRPA1 channels. This number is lower than that previously reported in astrocyte cultures (Shigetomi et al., 2012), but provides strong evidence for functional TRPA1 channels in astrocyte branches.

TRPA1 channels regulate astrocyte basal Ca^{2+} levels

Although TRPA1-mediated microdomain Ca^{2+} signals can be observed using Lck-GCaMP3, their function is to contribute to astrocyte basal Ca^{2+} levels as measured with cytosolic organic

Figure 2. Functional evidence that astrocyte branches express TRPA1 channels that mediate spotty Ca^{2+} signals. **A**, Representative traces of spontaneous spotty Ca^{2+} signals recorded from branches of astrocytes expressing Lck-GCaMP3 (Shigetomi et al., 2013). **B**, As in **A**, but in the presence of HC 030031 ($80 \mu\text{M}$). **C**, Cumulative probability plots for Ca^{2+} signal peak heights (dF/F), duration ($T_{0.5}$), and frequency. The cumulative probability plots are shifted to smaller amplitudes and lower frequencies in the presence of HC 030031. Note the two distributions are significantly different on the basis of a Kolmogorov–Smirnov test. Average data are presented in the text. **D**, Scatter plot shows how the number of spotty Ca^{2+} events measured per astrocyte with Lck-GCaMP3 decreases in the presence of HC 030031. **E**, Plots the number of spotty Ca^{2+} events measured as a function of distance from the soma. Note there is a consistent decrease in the number of Ca^{2+} events measured in the presence of HC 030031 throughout astrocyte territories, implying that the significant decrease shown in **E** does not occur at any specific distance from the soma. Rather, the HC 030031-sensitive Ca^{2+} events appear to be drawn from entire astrocytes.

Ca^{2+} indicator dyes (Shigetomi et al., 2012). Given that a modest $\sim 20\%$ of the microdomain signals were mediated by TRPA1 channels (Fig. 2), we tested for this possibility in adult slices. To this end, we recorded a baseline period of 5 min and then applied $80 \mu\text{M}$ HC 030031 in the bath and observed a significant drop in the baseline fluorescence of Fluo-4-loaded astrocytes (Fig. 3A, B; $-21 \pm 2\%$, $n = 42$; $p < 0.05$ using a paired Student's *t* test). This effect of HC 030031 was almost completely abolished in $\text{TRPA1}^{-/-}$ mice (Kwan et al., 2006) as seen in the cumulative probability plots and in the histogram (Fig. 3B; $-4 \pm 2\%$, $n = 28$; $p < 0.01$ using an unpaired Student's *t* test), indicating that HC 030031 acted via TRPA1 and not via some other mechanism (Shigetomi et al., 2012). These observations in adult mice extend our past work in young mice, and indicate that

Figure 3. Blocking TRPA1 channels reduces astrocyte basal Ca^{2+} levels. **A**, Graphs plot dF/F over time from astrocytes loaded with Fluo-4 in hippocampal slices from adult mice. Application of HC 030031 ($80 \mu\text{M}$) reduced the baseline fluorescence of astrocyte somata. Note that in these traces, some of the peaky Ca^{2+} transients have been clipped to more clearly show the drop in baseline Ca^{2+} . **B**, Cumulative probability plot of dF/F evoked by HC 030031 applications to astrocytes in acute hippocampal slices from WT and $\text{TRPA1}^{-/-}$ mice. Note the two distributions are significantly different on the basis of a Kolmogorov–Smirnov analysis. The bar graph summarizes the finding that HC 030031 reduces resting Ca^{2+} levels in astrocytes from WT hippocampal slices.

TRPA1 channels in astrocytes regulate the bulk cytosolic basal Ca^{2+} concentration of astrocytes (Shigetomi et al., 2012; Tong et al., 2013).

TRPA1 channel blockade reduced LTP and this was rescued by exogenous D-serine

Astrocytes are thought to both constitutively and actively release D-serine. However, the cellular mechanisms that regulate D-serine release are not fully understood (Oliet and Mothet, 2006, 2009; Rusakov et al., 2011; Henneberger et al., 2012). Although activity-dependent D-serine release through Ca^{2+} -dependent mechanisms has been proposed, recent data suggest that D-serine is also released via Ca^{2+} -dependent constitutive release. To explore the potential role of astrocyte TRPA1 channels, we determined whether HC 030031 affected LTP. We applied HC 030031 10 min before and during high-frequency electrical field stimulation of the Schaffer collaterals and monitored fEPSPs for 1 h. HC 030031 ($80 \mu\text{M}$) significantly suppressed LTP relative to control slices from WT mice at ~52–60 min postinduction (Fig. 4A,B). Control fEPSPs were potentiated to $171 \pm 11\%$ of baseline, whereas in the presence of HC 030031 they were potentiated to $137 \pm 7\%$ of baseline ($p < 0.05$, using unpaired Student's t tests; HC 030031 $n = 6$; WT $n = 7$).

In light of the finding that blocking TRPA1 channels reduces astrocyte Ca^{2+} levels (Shigetomi et al., 2012) (Fig. 3A,B), we hypothesized that Ca^{2+} entry via TRPA1 channels may permit D-serine release (Yang et al., 2003; Henneberger et al., 2010) and hence explain why HC 030031 reduced LTP. This hypothesis linking basal Ca^{2+} and D-serine release is based on the finding that Ca^{2+} buffers dialyzed selectively into astrocytes reduce D-serine levels (Henneberger et al., 2010; Kang et al., 2013). Consistent with previous reports (Henneberger et al., 2010), bath applications of D-serine ($10 \mu\text{M}$) did not affect LTP (Fig. 4C; $170 \pm 11\%$, $n = 6$, $p > 0.05$, using unpaired Student's t tests). However, bath applications of D-serine completely blocked the reduction of LTP caused by HC 030031 (Fig. 4B; $173 \pm 15\%$, $n = 6$, $p < 0.05$, using unpaired Student's t tests). This result demonstrates that the reduction of LTP observed upon blocking TRPA1

Figure 4. Blocking TRPA1 channels reduces LTP. **A**, fEPSP traces were recorded from the stratum radiatum before and after high-frequency stimulation (HFS; 2×100 Hz, inter-train interval 10 s). Traces are shown for several experiments at various time points before and after HFS. **B**, HFS-induced robust LTP in control experiments ($n = 7$). HC 030031 ($80 \mu\text{M}$, $n = 6$) suppressed LTP in a manner that was rescued by $10 \mu\text{M}$ D-serine ($n = 6$). **C**, D-Serine ($10 \mu\text{M}$) did not affect LTP ($n = 6$, $p = 0.876$). **D**, The “glycine site” antagonist DCKA ($10 \mu\text{M}$; $n = 6$) suppressed LTP. **E**, AITC ($100 \mu\text{M}$) did not affect LTP ($n = 7$). **F**, **G**, HC 030031 did not affect AMPAR-mediated fEPSPs (**F**) or presynaptic fiber volleys (**G**; $n = 7$).

channels can be rescued by exogenous D-serine, suggesting that TRPA1 channel function in astrocytes permits or causes the constitutive release of substantial amounts of D-serine, which in turn regulates LTP. We further tested this possibility by applying the NMDAR “glycine site” antagonist $10 \mu\text{M}$ 5,7-dichlorokynurenic acid (DCKA) (Yang et al., 2003; Henneberger et al., 2012) and found that it reduced LTP to levels indiscernible from the effect of HC 030031 (Fig. 4D). Together these evaluations strongly suggest that NMDAR-dependent LTP is regulated by endogenous D-serine release, which is sensitive to pharmacological block of astrocyte TRPA1 channels (Fig. 4B).

Recent studies using engineered mice show that increasing cytosolic Ca^{2+} levels within astrocytes does not affect LTP (Agulhon et al., 2010). In light of these data, we applied the TRPA1 agonist allyl isothiocyanate (AITC; $100 \mu\text{M}$) to hippocampal slices to determine whether this affected LTP (Shigetomi et al., 2012). Interestingly, we found that AITC increased short-term

post-tetanic potentiation, but did not affect LTP relative to control (Fig. 4E; $163 \pm 11\%$, $n = 6$, $p > 0.05$, using a paired Student's t tests), even though it significantly elevated astrocyte Ca^{2+} levels in $\sim 40\%$ of astrocytes (Shigetomi et al., 2012). Consistent with past work on store-mediated Ca^{2+} elevations (Agulhon et al., 2010), these data suggest that astrocyte Ca^{2+} elevations triggered by exogenous activation of TRPA1 channels do not detectably regulate LTP.

HC 030031 did not affect either basal fEPSPs or presynaptic fiber volleys (Fig. 4F, G) and did not change CA1 pyramidal neuron resting membrane potentials, membrane resistances, or action potentials (Shigetomi et al., 2012), arguing against effects of this molecule on presynaptic and postsynaptic neurons directly. The available literature also indicates that HC 030031 is a selective TRPA1 antagonist (McNamara et al., 2007; Eid et al., 2008).

TRPA1^{-/-} mice displayed reduced LTP that was rescued by D-serine

To further explore roles for TRPA1 channels in regulating LTP, we analyzed TRPA1^{-/-} deletion mice (Kwan et al., 2006). We started by examining basal excitatory synaptic transmission and found that the relationship between fEPSP slope and Schaffer collateral stimulation was indiscernible from WT control mice (Fig. 5A; $n = 11$ and 16 for TRPA1^{-/-} and WT mice, respectively). These data recall past work (Shigetomi et al., 2012) and indicate that basal excitatory synaptic transmission in TRPA1^{-/-} mice is normal.

We next examined WT and TRPA1^{-/-} mice and found that LTP was significantly reduced in the knock-out mice (Fig. 5B, D; $p < 0.01$ using unpaired Student's t tests; $n = 12$ and 16 for TRPA1^{-/-} and WT mice, respectively) to a level comparable to the effect of HC 030031 on WT mice (Fig. 4B). Moreover, LTP in the TRPA1^{-/-} mice was fully rescued to WT levels by the bath application of $10 \mu\text{M}$ D-serine (Fig. 5C, D; $n = 6$ and 5 for TRPA1^{-/-} and plus D-serine conditions, respectively). We also determined whether HC 030031 reduced LTP in the TRPA1^{-/-} mice and found that it did not (Fig. 5D; $n = 7$ and 6 for TRPA1^{-/-} and plus HC 030031 conditions, respectively). This latter result is important because it provides strong evidence that the effects of HC 030031 in WT mice (Fig. 4) are due to actions via TRPA1 and not some other mechanism.

Recent studies show that LTP is normal in IP3R2^{-/-} mice (Agulhon et al., 2010), implying that cytosolic Ca^{2+} store signals are not crucial for LTP. In accord, we also found that LTP was the same for IP3R2^{-/-} and WT littermate control mice (Fig. 5D; $n = 7$ and 10 for WT and IP3R2^{-/-} mice, respectively). Thus our data show that blockade (Fig. 4) or deletion (Fig. 5) of the TRPA1 channel-mediated pathway significantly reduces LTP, but that deletion of the IP3R2-mediated cytosolic store pathway does not, emphasizing how distinct astrocyte Ca^{2+} sources have separable effects on LTP.

Figure 5. Reduced LTP in TRPA1^{-/-} mice. **A**, Traces for fEPSPs recorded from hippocampal slices harvested from WT and TRPA1^{-/-} mice. The relationship between fEPSP slope and presynaptic fiber volley for WT and TRPA1^{-/-} mice is also shown. The inset shows an average fEPSP. **B**, LTP was suppressed in TRPA1^{-/-} mice relative to WT controls. **C**, Suppressed LTP in TRPA1^{-/-} mice was restored by bath applications of $10 \mu\text{M}$ D-serine. **D**, Summary bar graph showing the degree of LTP in control recordings and under the various conditions indicated. HC 030031 ($80 \mu\text{M}$) failed to suppress LTP in TRPA1^{-/-} mice and LTP was equivalent in IP3R2^{-/-} and WT littermate mice.

Controls for TRPA1 blockade: ruling out effects of GABA

Recently, we showed that blocking astrocyte TRPA1 channels reduced phasic miniature IPSCs and increased tonic GABA currents onto interneurons of the hippocampus (Shigetomi et al., 2012). The mechanism was reduced GABA transport by astrocyte GAT-3 GABA transporters leading to elevated ambient GABA levels in the extracellular space. As such, the effects of TRPA1 blockade could be mimicked by blocking GAT-3 transporters (Shigetomi et al., 2012). Might this coincidental altered inhibitory interneuron synaptic transmission contribute to the LTP effects (Fig. 4) observed by blocking TRPA1? We considered this unlikely because HC 030031 was only applied for 10 min in the LTP experiments (Figs. 4, 5) and because the effect on inhibitory synapses was limited to interneurons. Nonetheless, we repeated the LTP experiments with the GAT-3 blocker β -alanine ($100 \mu\text{M}$; Fig. 6A, D; $n = 5$), with $5 \mu\text{M}$ GABA in the bath to mimic the effects of elevated tonic GABA levels (Fig. 6B, D; $n = 7$) and with both together (Fig. 6C, D; $n = 5$). In all three conditions LTP was normal (Fig. 6; $p > 0.05$ using unpaired Student's t tests for each pair in Fig. 6D). We suggest, therefore, that the effects of TRPA1 blockade on LTP described in preceding sections (Figs. 4, 5) cannot be accounted for by coincidental effects on inhibitory synapses.

Measuring *in situ* D-serine levels using D-serine biosensor electrodes

Since the electrophysiological studies strongly suggest that blockade or deletion of TRPA1 channels reduced the extracellular levels of D-serine, we next sought to measure D-serine levels directly using D-serine biosensor electrodes (Dale et al., 2005) (Fig. 7A; see Materials and Methods). Our calibration experiments show that the biosensor electrodes can reliably detect D-serine levels between 0.4 and $25 \mu\text{M}$ (Fig. 7B). This sensitivity is appropriate

Figure 6. LTP was not altered when GAT-3 was blocked or when GABA was applied in the bath. **A–C**, LTP was normal and indiscernible from WT controls in slices treated with (**A**) the GAT-3 blocker β -alanine (100 μ M), (**B**) GABA (10 μ M), and (**C**) both β -alanine and GABA together. **D**, Summary bar graph of the findings shown in **A–C**.

for our studies because we expect the amount of D-serine will be $<10 \mu$ M (Schell, 2004) (Figs. 4B, 5D).

We started with the biosensor electrodes positioned above hippocampal slices. Upon moving the electrode $\sim 200 \mu$ m into the slice, we measured a large increase in biosensor current, which we converted to D-serine concentration ([D-serine]; Fig. 7B; $n = 8$). Thus, we measured the “Peak [D-serine] on entering the slice” at $\sim 6 \mu$ M (Fig. 7C–E). We associate this transient signal as D-serine release during damage caused by the insertion of the 50μ m diameter electrodes. In accord, this rapid increase in [D-serine] declined over minutes and reached a steady-state level in the slice. We estimated this steady-state level by removing the electrode from the slice, providing a measure of “Steady-state [D-serine] in the slice,” which was $\sim 1 \mu$ M (Fig. 7C; $n = 8$). We repeated these experiments in $TRPA1^{-/-}$ mice ($n = 6$). Representative traces are shown in Fig. 7D. By quantifying peak and steady-state [D-serine] levels we found that the peak [D-serine] was not significantly different between WT and $TRPA1^{-/-}$ mice, and that HC 030031 application to WT slices did not change peak [D-serine] levels (Fig. 7E; $p > 0.05$ using an unpaired Student’s t test). In contrast, we found that the steady-state [D-serine] in the slices was significantly lower in $TRPA1^{-/-}$ slices, as well as in WT slices treated with HC 030031 (in relation to control WT slices; Fig. 7C,D,F; $n = 6$ and 7 ; $p < 0.01$ using an unpaired Student’s t test). Together, these data provide strong evidence that the [D-serine] within the slices is $\sim 1 \mu$ M and that pharmacological block or deletion of TRPA1 significantly reduces this to $\sim 0.4 \mu$ M (Fig. 7F).

Synaptic NMDAR/AMPA ratios are altered when TRPA1 channels are blocked or deleted

Using whole-cell voltage-clamp recording we evaluated how TRPA1 channels contribute to the NMDAR and AMPAR components of evoked EPSCs in pyramidal neurons (measured as the NMDAR/AMPA ratio), and measured NMDAR/AMPA ratios to cancel the variability of currents between cells. We measured NMDA and AMPA EPSCs simultaneously by varying the holding voltage (-80 mV for AMPA and $+40$ mV for NMDA EPSCs; Fig. 8A) and explored the roles of TRPA1 channels using HC 030031 in WT mice as well as by comparing between WT and $TRPA1^{-/-}$ mice. From a control set of recordings, the NMDA/AMPA ratios were 0.015 ± 0.0045 and 0.543 ± 0.027 at -80 and $+40$ mV, respectively ($n = 15$ cells). We found that the NMDAR/AMPA ratio was significantly smaller in $TRPA1^{-/-}$ mice ($n = 17$) than WT mice ($n = 15$), and that this was restored to WT levels by bath application of D-serine (Fig. 8B; $n = 8$; $p < 0.01$ using an unpaired Student’s t test). Interestingly, D-serine did not change the NMDAR/AMPA ratio in WT mice (Fig. 8B; $n = 8$) implying that the “glycine site” of NMDA receptors may be saturated, which recalls data in Figures 4 and 5. Moreover, in WT mice HC 030031 reduced the NMDAR/AMPA ratio ($n = 9$ from four mice; $p < 0.01$ using an unpaired Student’s t test)

and this effect was absent in the $TRPA1^{-/-}$ mice ($n = 8$ cells from 4 mice; $p > 0.05$ using an unpaired Student’s t test), confirming that HC 030031 acts via TRPA1 (Fig. 8C). Finally, bath application of D-serine prevented the effects of HC 030031 on WT mice ($n = 8$) and rescued the reduced NMDAR/AMPA ratio observed in $TRPA1^{-/-}$ mice back to WT control levels such that HC 030031 was without additional effect (Fig. 8D; $n = 8$; $p > 0.05$ using an unpaired Student’s t test). Together, these experiments provide compelling evidence that blocking or deleting TRPA1 channels changes the NMDA component of evoked EPSCs recorded from CA1 pyramidal neurons in a D-serine-dependent manner.

Discussion

The present study was motivated by the recent discovery that hippocampal astrocytes express TRPA1 channels (Shigetomi et al., 2012; Tong et al., 2013; Kimura et al., 2013; Scimemi, 2013) and there are four main findings from it. First, astrocyte TRPA1 channels underlie $\sim 20\%$ of the ongoing spontaneous Ca^{2+} microdomain signals (Shigetomi et al., 2013), but contribute significantly to resting basal Ca^{2+} levels in stratum radiatum region astrocytes from adult mice. Second, blocking or deleting TRPA1 channels reduces NMDAR-dependent LTP in a manner that is dependent on extracellular D-serine levels. Third, blocking or deleting TRPA1 channels reduces extracellular D-serine levels. Fourth, blocking or deleting TRPA1 channels reduces the NMDAR component of evoked EPSCs. Overall, our data suggest that astrocyte TRPA1 channels are endogenous regulators of as-

trocyte D-serine mediated signaling (MUSTAFA et al., 2004; OLIET and MOTHET, 2006, 2009).

We found that activating TRPA1 channels did not affect LTP, whereas this did result in elevations of astrocyte Ca^{2+} levels (Shigetomi et al., 2012). A likely explanation may be that close to $\sim 7 \mu\text{M}$ D-serine is normally found in the extracellular fluid, which may be sufficient to nearly saturate hippocampal NMDA receptors (Schell, 2004). If so, elevated astrocyte Ca^{2+} levels would be inconsequential even if they resulted in additional D-serine release. A further question arises from our work: namely are TRPA1 channels unique or autonomous in their ability to regulate D-serine release? We argue that this is unlikely to be the case. Thus, it is already known that a specific glutamate receptor-mediated molecular cascade is necessary to evoke additional D-serine release from astrocytes (MOTHET et al., 2000; Kim et al., 2005) and it is therefore possible that TRPA1 activation failed to cause any more D-serine release because the TRPA1 pathway may not activate the requisite signaling machinery within astrocytes. Clearly other parallel pathways regulating D-serine release exist (MOTHET et al., 2000; Kim et al., 2005) and TRPA1 channels are not unique in this regard. Broadly, these findings are consistent with data showing that activation of a Ca^{2+} -mobilizing G-protein-coupled receptor that was exogenously expressed within astrocytes, or blocking intracellular store-mediated Ca^{2+} signals, also did not affect LTP in the hippocampal CA1 region (Aguilhon et al., 2010). In contrast, astrocyte Ca^{2+} elevations mediated by intracellular stores are involved in LTP in the cortex (Takata et al., 2011). What explains these differences? It is likely that brain region-specific differences between the cortex and hippocampus reflect astrocyte diversity in different parts of the brain (Zhang and Barres, 2010; Oberheim et al., 2012). Moreover, empirical data suggest that D-serine levels in the cortex are lower than those in the hippocampus and consequently that the glycine site of NMDARs in the cortex may not normally be saturated with D-serine (Fossat et al., 2012). This largely supports the finding that store-mediated Ca^{2+} signals within astrocytes contribute to D-serine release to regulate cortical LTP (Takata et al., 2011). Along these lines, our data suggest that D-serine levels in the CA1 region of the hippocampus are relatively high, perhaps because astrocytes in this region contain the highest amounts of D-serine (Schell et al., 1997).

Nonetheless, with the aforementioned considerations in mind, in future work it will be important to activate TRPA1 channels with selective agonists and determine whether such manipulations can cause more D-serine release and also affect LTP. At this juncture, these experiments are not possible because no selective TRPA1 agonists exist and the “pungent”

Figure 7. Extracellular D-serine levels are regulated by TRPA1 channel function. **A**, Photograph of a hippocampal slice from a 2-month-old mouse with biosensor electrodes placed in the stratum radiatum. This diagram illustrates how the biosensors work. **B**, Representative traces and average data for biosensor electrode calibration. **C**, Representative traces showing measurement of [D-serine] with biosensor electrodes when the biosensor was positioned above the slice, moved into the slice, and then withdrawn from the slice. This protocol results in two measurements of [D-serine] indicated in blue and red text. **D**, As in **C**, but for recordings from a *TRPA1*^{-/-} mouse. **E**, The bar graph summarizes the peak [D-serine] for three experimental conditions. There were no significant differences. **F**, The bar graph summarizes the steady-state [D-serine] within the slice for three experimental conditions. Note that [D-serine] levels are reduced in WT slices treated with HC 030031 and in slices from *TRPA1*^{-/-} mice.

molecules that nonspecifically activate them have multiple attendant actions (e.g., mustard oil, nicotine, formaldehyde, cinnamon oil, hydrogen sulfide). Specifically, it has been shown that the commonly used TRPA1 agonist AITC (the active substance of mustard oil) still produces responses in TRPA1 deletion mice (Kwan et al., 2006), proving that such molecules are of limited use to explore mechanisms in multicellular preparations such as brain slices, although they are adequate for biophysical studies of recombinant receptors in HEK293 cells and *Xenopus* oocytes. This is the main reason why we focused on blocking TRPA1 channels with a selective antagonist (HC 030031), and why we also focused on using knock-out mice to explore specific roles for TRPA1 channels. Although cautious, we believe this was the right approach to take. Nonetheless, our findings should be interpreted with all these considerations in mind and, of course, it will be interesting to return to this issue when selective TRPA1 agonists are discovered or synthesized.

Figure 8. Blocking TRPA1 channels regulates the NMDAR to AMPAR ratio for evoked EPSCs. **A**, Traces showing the AMPA and NMDA components of evoked EPSCs measured from CA1 pyramidal neurons (average of 5 sweeps). **B**, NMDAR/AMPA ratios (recorded at +40 mV) in CA1 pyramidal cells from 17 *TRPA1*^{-/-} neurons (*n* = 4 mice) and 15 WT neurons cells (*n* = 4 mice). The NMDAR-mediated component of the EPSC was significantly reduced in *TRPA1*^{-/-} neurons (*p* < 0.01). The same experiment was done in the presence of 10 μ M D-serine (pink bars). Results are from 10 neurons from three WT mice and 11 neurons from three *TRPA1*^{-/-} mice are shown. In the presence of D-serine the NMDAR/AMPA ratios in *TRPA1*^{-/-} cells were not significantly different from WT (*p* = 0.886). In *TRPA1*^{-/-} neurons, the ratios are significantly higher in the presence of D-serine (*p* < 0.01) while D-serine has no effect on the NMDAR component of EPSCs in WT neurons cells (*p* = 0.215). **C**, A 10 min bath application of 80 μ M HC 030031 inhibits the NMDAR-mediated component of the EPSCs in WT neurons (paired *t* test comparison, *p* < 0.01, *n* = 9 cells) but has no effect on the NMDAR-mediated component of EPSCs from *TRPA1*^{-/-} mice (paired *t* test comparison, *p* = 0.488, *n* = 8 cells). **D**, HC 030031 has no effect on the NMDAR-mediated EPSCs in WT (8 cells) or *TRPA1*^{-/-} neurons (8 cells) when applied in the presence of 10 μ M D-serine.

In future studies, it will be interesting to delete TRPA1 channels from all as well as specific subpopulations of hippocampal astrocytes and explore synaptic plasticity using the experimental approaches and controls reported herein. However, at this juncture such experiments are not possible and at least two advances are needed for them to commence. First, a knock-in mouse line expressing a floxed allele of TRPA1, in which key exons are flanked by loxP sites, needs to be generated and rigorously characterized. Second, genetic strategies are needed to selectively express and inducibly activate Cre recombinase within astrocytes. We endeavor to develop the appropriate genetic tools and return to this issue in the years ahead.

We found that blocking or deleting TRPA1 channels significantly reduced NMDAR-dependent LTP and the NMDA component of evoked EPSCs in a manner that was completely rescued by exogenous D-serine. Moreover, blocking or genetically deleting TRPA1 channels also reduced the concentration of D-serine within brain slices, providing strong evidence that TRPA1 channels regulate D-serine release. However, a note of caution is necessary when precisely interpreting absolute D-serine concen-

trations measured using biosensor electrodes. As such the 50 μ M biosensor electrodes provide a measure of ambient D-serine levels in the extracellular fluid rather than at synaptic NMDARs. Consistent with this view, light and electron microscopy shows that NMDAR-expressing synapses are often ensheathed by D-serine containing astrocyte processes (Schell et al., 1995, 1997, 2004), implying that synaptic D-serine concentrations are likely to be higher than those amenable to detection with biosensor electrodes. Nonetheless, our experiments provide strong evidence that blocking or deleting TRPA1 channels reduces extracellular D-serine levels in the hippocampus.

By demonstrating how TRPA1-mediated astrocyte basal Ca^{2+} levels regulate LTP via D-serine release and confirming that intracellular store signals do not (Agulhon et al., 2010), our studies highlight the importance of studying the full diversity of astrocyte Ca^{2+} signals in relation to their potential physiological roles. As such, it will be important to embrace and rigorously explore the concept of astrocyte heterogeneity and calcium signal diversity (Zhang and Barres, 2010; Oberheim et al., 2012) in future experiments *in situ* and *in vivo*. From this perspective, our study builds on recent work demonstrating the existence of distinct types of Ca^{2+} signals in Bergmann glia (Nimmerjahn et al., 2009) and work showing that quantifiably similar Ca^{2+} signals have distinct downstream consequences in cell culture and *in situ* (Bowser and Khakh, 2007; Shigetomi et al., 2008). Clearly then, Ca^{2+} does not appear to be an all-or-none binary signal within astrocytes (Tong et al., 2013) and perhaps there is little contradiction in past studies that

have explored distinct aspects of astrocyte Ca^{2+} signaling in relation to LTP (Agulhon et al., 2010; Henneberger et al., 2010).

In summary, the recent discovery and molecular identity of an astrocyte transmembrane Ca^{2+} flux pathway mediated by TRPA1 channels provided a new opportunity for exploring the role of astrocytes in synaptic plasticity (Henneberger et al., 2010). Overall, our findings show that TRPA1 channels are expressed in adult astrocytes where they contribute markedly to resting intracellular Ca^{2+} levels. Importantly, basal, but not elevated, TRPA1-mediated astrocyte Ca^{2+} levels are important for NMDAR-dependent forms of LTP in the hippocampus, because they appear to passively drive the release of the D-serine (Schell et al., 1995, 1997). Such a pathway has not been considered in past astrocyte studies (Agulhon et al., 2008), which have focused on elevations due to intracellular store-mediated Ca^{2+} release (Agulhon et al., 2008, 2010). In contrast, the data reported herein and in our past work (Shigetomi et al., 2012) suggest that the basal Ca^{2+} concentration of astrocytes is important to control what appear to be homeostatic functions (Tong et al., 2013). Thus, in the present study we show that astrocyte TRPA1 channels regulate

constitutive D-serine release, whereas previously we showed that they also regulate GABA uptake (Shigetomi et al., 2012; Tong et al., 2013). However, both these mechanisms contribute significantly to neuronal function, albeit in a neuromodulatory capacity. Along with gliotransmission (Haydon, 2001; Halassa and Haydon, 2010), these findings emphasize the diversity of mechanisms that astrocytes may use to control/regulate neurons and microcircuits.

Interestingly, past work has shown that the basal Ca^{2+} level of astrocytes is significantly elevated in models of Alzheimer's disease (Kuchibhotla et al., 2009). It will thus be interesting to extend our studies and evaluate if TRPA1 channel fluxes, and the ensuing downstream neuronal consequences, contribute to cognition (Turpin et al., 2011), traumatic injury (Mustafa et al., 2010), and brain disorders (Basu et al., 2009; Nedergaard et al., 2010), circumstances in which D-serine is thought to be involved (Mustafa et al., 2004). If so, astrocyte TRPA1 channels may be valuable therapeutic targets for brain disorders.
