

## Journal Club

**Editor's Note:** These short reviews of recent *JNeurosci* articles, written exclusively by students or postdoctoral fellows, summarize the important findings of the paper and provide additional insight and commentary. If the authors of the highlighted article have written a response to the Journal Club, the response can be found by viewing the Journal Club at [www.jneurosci.org](http://www.jneurosci.org). For more information on the format, review process, and purpose of Journal Club articles, please see <http://jneurosci.org/content/preparing-manuscript#journalclub>.

## Unique Maturation Trajectories of Basket and Chandelier Cells in the Neocortex

 Srikanth Ramaswamy

Blue Brain Project, Ecole Polytechnique Fédérale de Lausanne, Biotech Campus, CH 1202, Geneva, Switzerland  
Review of Miyamae et al.

In the mature brain, a small but diverse group of inhibitory neurons controls the output of an overwhelming majority of excitatory neurons. Within this diverse group, parvalbumin-expressing (PV<sup>+</sup>) neurons form the dominant inhibitory system (Rudy et al., 2011). In most brain regions, including the neocortex, PV<sup>+</sup> neurons comprise basket cells (BCs) and chandelier cells (ChCs). BCs selectively innervate the perisomatic region of target cells to bring about fast and powerful inhibition and, thus, influence cortical function and dysfunction (Kawaguchi and Kubota, 1997; Markram et al., 2004). For example, BCs provide feedforward inhibition in the neocortex, maintain high-frequency cortical oscillations (Pouille and Scanziani, 2001; Bartos et al., 2007; Cardin et al., 2009), and are implicated in cognitive diseases, such as schizophrenia (Lewis et al., 2005; Gonzalez-Burgos and Lewis, 2008). ChCs have an exquisite axonal morphology that enables them to synapse specifically on to the axon initial segment of target cells and strategically control spiking activity (Somogyi et al.,

1982). It is thought that the malfunction of ChCs can trigger temporal lobe epilepsy (DeFelipe, 1999; Zhu et al., 2004).

The varied but pivotal roles played by BCs and ChCs in cortical function suggest that the rate at which they develop morphologically and physiologically is fundamental in the emergence of cognitive skills and abilities. Although previous studies have attempted to characterize the developmental time course of PV<sup>+</sup> neurons in the cortex, they have exclusively focused either on BCs or ChCs, never examining both together (Wang et al., 2002; Okaty et al., 2009; Taniguchi et al., 2013). Therefore, an important question is the following: how do BCs and ChCs mature relative to each other to shape cognitive function? To fill this knowledge gap, Miyamae et al. (2017) assessed the morphological and physiological development of BCs and ChCs between postnatal day 8 (P8) and P73 using acute slices obtained from the prefrontal cortex (PFC) of transgenic mice expressing green fluorescent protein exclusively in PV<sup>+</sup> neurons.

Miyamae et al. (2017) discovered that, between ~P12, before the onset of puberty, and ~P73, by young adulthood, BCs were found throughout layers 2–5 (L3/5; note that L4 is absent in mouse PFC), whereas ChCs were mostly restricted to L1/L2. The authors then asked how the morphologies of BCs and ChCs, which innervate distinct domains of their target cells, develop relative to each other.

At P8, BCs in L1/L2 showed basket-like axonal arbors extending horizontally, whereas L1/L2 ChCs had ascending candlestick-like axons but lacked their hallmark axon cartridges. Axons in L1/L2 BCs and ChCs were fully formed by P28. Dendrites of L1/L2 BCs and ChCs were mature between P12 and P15, and those of L3/5 BCs had developed by P28.

Previous work has shown that the maturation of excitatory synaptic drive influences signaling mechanisms in BCs and ChCs (Hu et al., 2014). Therefore, in the next set of experiments, Miyamae et al. (2017) looked at how the amplitude and frequency of spontaneous EPSCs (sEPSCs) in these cells changed over time. At P12, sEPSCs in L1/L2 BCs and ChCs were similar in amplitude and frequency. However, by P30, the amplitude of sEPSCs did not change in L1/L2 BCs and ChCs, whereas their frequency was significantly higher in L1/L2 BCs, indicating markedly different timescales in their synaptic maturation. Miyamae et al. (2017) conjectured that the age-related increase in sEPSC frequency in L1/L2 BCs could be due to a higher release probability of glutamate. They investigated whether the release probability of glutamate in L1/L2 BCs increased with age by measuring the short-term depression of EPSCs. The authors found that the magnitude of synaptic depression did not increase with age in L1/L2 BCs, indicating that the release probability of glutamate was not age-

dependent. Miyamae et al. (2017) also compared the maturation of sEPSC amplitude and frequency in L3/5 BCs and L1/L2 BCs. They observed that, at P12, the amplitude of sEPSCs was similar in L3/5 BCs and L1/L2 BCs, but the frequency in L3/5 BCs was ~66% higher than that in L1/L2 BCs, suggesting that excitatory synaptic drive matures earlier in L3/5 BCs than in L1/L2 BCs. By P30, the amplitude of sEPSCs was similar between these cells, but the frequency remained higher in L3/5 BCs compared with L1/L2 BCs.

The results presented by Miyamae et al. (2017) on the absence of age-related changes in short-term depression complement previous findings on the maturation of synaptic physiology in neocortical pyramidal cells (Zhang, 2004). The short-term dynamics of synaptic connections between neocortical pyramidal cells has been shown to be age-dependent—synapses are strongly depressing at puberty (P12) but they gradually transition to being facilitating during adulthood (~P50) (Etherington and Williams, 2011; Ramaswamy and Markram, 2015). Interestingly, Miyamae et al. (2017) found that the short-term dynamics of excitatory synapses onto L1/L2 BCs and ChCs remained robustly depressing from puberty to adulthood. For a train of incoming stimuli, depressing synapses show the strongest response to the first input, followed by an exponential decrease in response strength and reliability for subsequent inputs (Abbott et al., 1997). Therefore, preserving short-term depression of synaptic input on to L1/L2 BCs and ChCs throughout development could provide these cells with the excitatory drive required to elicit the strongest response to the first input, and reliably inhibit neighboring neurons.

Miyamae et al. (2017) characterized the development of synaptic physiology in BCs and ChCs by performing experiments in cortical slices *in vitro* where the level of  $Ca^{2+}$  in the extracellular ionic composition is typically high (~2 mM). However, extracellular  $Ca^{2+}$  in the intact cortex *in vivo* is significantly lower (~1.2 mM). Extracellular  $Ca^{2+}$  levels can strongly modulate neurotransmitter release probability and, consequently, cortical activity (Borst, 2010). In addition, cortical state *in vivo* is regulated by numerous neuromodulators, including acetylcholine, dopamine, and noradrenaline, among many others (Harris and Thiele, 2011; Zagha and McCormick, 2014). Therefore, it would be important for future work to investigate the effects of low  $Ca^{2+}$  levels

and different neuromodulators on the maturation of synaptic properties in BCs and ChCs under experimental conditions that more closely mimic the extracellular ionic composition and cortical state *in vivo*.

BCs and ChCs not only have conspicuous morphologies but also show a prominent fast-spiking pattern of activity (Kawaguchi and Kubota, 1997). Given that the morphological development of BCs and ChCs follows distinct time scales, how do their physiological properties compare over this developmental period? In a final set of experiments, Miyamae et al. (2017) catalogued age-related changes of several electrophysiological variables contributing to the fast-spiking phenotype. The authors compared the maturation of fast-spiking properties in L1/L2 BCs and ChCs and found that they were underdeveloped at P12 and fully developed at P30. Four of the 10 electrophysiological variables measured by the authors (the spike half-width and threshold for initiation, membrane time-constant, and the frequency-current response) matured more slowly in L1/L2 ChCs than in L1/L2 BCs. Comparison of the developmental time course of the same four variables from puberty to adulthood in L1/L2 and L3/5 BCs revealed that fast-spiking features matured at similar rates between the two populations, however, commencing earlier in L3/5 BCs.

It is thought that fast-spiking activity in BCs and ChCs enables frequency tuning and synchrony of network oscillations in the gamma band (30–100 Hz) (Bartos et al., 2007). Gamma oscillations have been proposed to regulate higher brain functions, such as visual attention, memory formation, and sensory processing (Buzsáki and Wang, 2012). In the cortex, low-frequency asynchronous gamma activity appears around P8, which develops to high-frequency synchronous activity by P20 (Doischer et al., 2008). The development of the fast-spiking phenotype in BCs and ChCs could influence the maturation of gamma oscillations. For example, at P12, the frequency-current response in L1/L2 BCs develops faster than in ChCs. This implies that, for a given amount of stimulus current, spiking activity is higher in BCs than in ChCs. Therefore, differential development of fast-spiking features could enable BCs to generate high-frequency synchronous gamma activity, whereas ChCs could influence low-frequency asynchronous oscillations. Importantly, the findings by Miyamae et al. (2017) on the later time course of physiological maturation of ChCs versus BCs is consistent

with a recent study identifying delayed maturation of synaptic output in ChCs compared to BCs (Rinetti-Vargas et al., 2017). Miyamae et al. (2017) provide a framework to link developmental changes in the morphological and physiological properties of BCs and ChCs to higher-order cortical function.
