Voltage-gated T-type Ca<sup>2+</sup> (Ca<sub>v</sub>3) channels regulate diverse physiological events, including neuronal excitability, and have been linked to several pathological conditions such as absence epilepsy, cardiovascular diseases, and neuropathic pain. It is also acknowledged that calcium/calmodulin-dependent protein kinase II and protein kinases A and C regulate the activity of T-type channels. Interestingly, peripheral nerve injury induces tactile allodynia and upregulates Ca<sub>v</sub>3.2 channels and cyclin-dependent kinase 5 (Cdk5) in dorsal root ganglia (DRG) and spinal dorsal horn. Here, we report that recombinant Ca<sub>v</sub>3.2 channels expressed in HEK293 cells are regulatory targets of Cdk5. Site-directed mutagenesis showed that the relevant sites for this regulation are residues S561 and S1987. We also found that Cdk5 may regulate Ca<sub>v</sub>3.2 channel functional expression in rats with mechanical allodynia induced by spinal nerve ligation (SNL). Consequently, the Cdk5 inhibitor olomoucine affected the compound action potential recorded in the spinal nerves, as well as the paw withdrawal threshold. Likewise, Cdk5 expression was upregulated after SNL in the DRG. These findings unveil a novel mechanism for how phosphorylation may regulate Ca<sub>v</sub>3.2 channels and suggest that increased channel activity by Cdk5-mediated phosphorylation after SNL contributes nerve injury-induced tactile allodynia.

**Key words:** allodynia; calcium channels; neuropathic pain; spinal nerve ligation

## Significance Statement

Neuropathic pain is a current public health challenge. It can develop as a result of injury or nerve illness. It is acknowledged that the expression of various ion channels can be altered in neuropathic pain, including T-type Ca<sup>2+</sup> channels that are expressed in sensory neurons, where they play a role in the regulation of cellular excitability. The present work shows that the exacerbated expression of Cdk5 in a preclinical model of neuropathic pain increases the functional expression of Ca<sub>v</sub>3.2 channels. This finding is relevant for the understanding of the molecular pathophysiology of the disease. Additionally, this work may have a substantial translational impact, since it describes a novel molecular pathway that could represent an interesting therapeutic alternative for neuropathic pain.

## Introduction

Pain is a relevant clinical problem and, in its chronic form, can represent a serious disability condition. According to the World

Health Organization, ~20% of primary care patients have chronic pain (Yawn et al., 2009). This condition results from injury and/or abnormal functioning of the nervous system that

begins to interpret normal sensory stimuli (i.e., temperature, touch) as painful sensations (Millan, 1999; Woolf, 2004). These stimuli are detected by a subpopulation of primary afferent fibers (C and A $\delta$ ) called nociceptors whose somas are located in the dorsal root ganglia (DRG; Basbaum et al., 2009). Sensory neurons have a pseudounipolar morphology with a peripheral branch that innervates its target tissue and a central branch that establishes synapses in the dorsal horn of the spinal cord (Millan, 1999; Woolf, 2004; Todd, 2010).

Although the pathophysiology of neuropathic pain is far from being understood, recent studies suggest that voltage-gated Ca<sup>2+</sup> (Ca<sub>v</sub>) channels play crucial roles in nociceptive signaling. A subpopulation of DRG neurons does not express high voltage-activated (HVA) currents but do have low-threshold (T-type) currents. Most small-diameter DRG neurons and the T-rich cells express capsaicin-sensitive T-currents and are positive for lectin IB4, suggesting their nociceptive function. T-channels are also present in medium-diameter DRG neurons (Nelson et al., 2006, 2007). It has been reported that Ca<sub>v</sub>3.2 is the most abundant isoform of the T-channels in nociceptive neurons of small and medium diameters (Scroggs and Fox, 1992; Talley et al., 1999), and are present in the central terminals of peptidergic and non-peptidergic fibers that synapse in the dorsal horn of the spinal cord (Jacus et al., 2012). Also, these channels are expressed in the cutaneous mechanoreceptors of low-threshold (A $\delta$  and C) fibers both in the initial segment of the axon and in the peripheral terminals that make contact at presynaptic and postsynaptic levels in the spinal cord (François et al., 2015).

T-type channels are regulated by phosphorylation (Lambert et al., 2006; Chemin et al., 2007; Blesneac et al., 2015). The intracellular loop connecting domains II and III of the pore-forming subunit is an important modulation site for different protein kinases, including calcium/calmodulin-dependent protein kinase II and protein kinases A and C, that generally increase current density (Yao et al., 2006; Iftinca and Zamponi, 2009; Zhang et al., 2013). Also, a role for cyclin-dependent kinase 5 (Cdk5) in the regulation of T-channels in neuroblastoma N1E-115 cells and recombinant Ca<sub>v</sub>3.1 channels expressed in HEK293 cells has been recognized (Calderón-Rivera et al., 2015). Cdk5 is a ubiquitously expressed kinase that forms a catalytic complex with its activators p35 and p39 (McLinden et al., 2012).

Interestingly, an increase in Ca<sub>v</sub>3.2 channels and T-currents has been observed in DRG and dorsal horn neurons from rats with neuropathic pain (Jagodic et al., 2008; Takahashi et al., 2010; Wen et al., 2010). Consistent with this, intrathecal administration of antisense Ca<sub>v</sub>3.2 oligonucleotides or the T-channel blocker mibefradil prevents neuropathic pain induced by sciatic nerve constriction or DRG compression (Dogrul et al., 2003; Bourinet et al., 2005; Wen et al., 2010). Likewise, an increase in Ca<sub>v</sub>3.2 channel and T-current expression has also been observed in DRG and spinal cord neurons from animals with diabetic neuropathy, and its knockdown in the DRG prevents hyperalgesia (Jacus et al., 2012; Todorovic and Jevtovic-Todorovic, 2013).

Here, we investigated the modulation of T-channels by the Cdk5/p35 complex expressed in HEK293 cells, and their role in the excitability of the sensory fibers, by analyzing the compound action potential (cAP) evoked by stimulation of the spinal nerve L5 and recorded in the corresponding dorsal root of animals with allodynia induced by ligation of the spinal nerves L5-L6. We found an increase in the amplitude of the C component of the cAP, related to an increase in the functional expression of the Ca<sub>v</sub>3.2 channels induced by Cdk5-mediated phosphorylation. In addition, intrathecal administration of a Cdk5 inhibitor allevi-

ated mechanical allodynia and decreased the C component of the cAP.

## Materials and Methods

**Cell culture.** Human embryonic kidney (HEK) 293 cells were grown as previously described (Calderón-Rivera et al., 2015). In brief, untransfected cells were kept in DMEM-HG culture medium containing 25 mM glucose, supplemented with 10% fetal bovine serum (FBS), 2 mM L-glutamine, and antibiotics. HEK293 cells stably expressing the Ca<sub>v</sub>3.2 channels were maintained in culture in DMEM supplemented with 1 mg/ml G418 (Thermo Fisher Scientific), 10% FBS, and penicillin-streptomycin (100 U/ml) also at 37°C in a 5% CO<sub>2</sub>-95% air humidified atmosphere. The cells were treated with olomoucine at a final concentration of 100  $\mu$ M during 48 h or with DMSO (as control). Both cell cultures were reseeded by mechanical dispersion every week.

**Whole-cell patch-clamp electrophysiology.** HEK293 cells were subjected to the whole-cell mode of the patch-clamp technique using an Axopatch 200B amplifier as described previously (Avila et al., 2004; Calderón-Rivera et al., 2015). Current signals were filtered and digitized at 2 and 5.7 kHz, respectively, and analyzed with pCLAMP software (Molecular Devices). The bath recording solution contained the following (in mM): either 5 CaCl<sub>2</sub> (stably transfected cells) or 10 BaCl<sub>2</sub> (transiently transfected cells), 125 TEA-Cl, 10 HEPES, and 10 glucose, pH 7.3. The pipette solution contained the following (in mM): 110 CsCl, 5 MgCl<sub>2</sub>, 10 EGTA, 10 HEPES, 4 Mg-ATP, and 0.1 GTP, pH 7.3. Recording pipettes with resistance values in the range of 2–3 M $\Omega$  were used. Both the linear leak and the parasitic capacitance components were subtracted using a P/4 standard protocol. Membrane capacitance (C<sub>m</sub>) was determined as previously described and used to normalize currents (Avila et al., 2004).

Current activation curves were fitted using the following equation:  $G/G_{\max} = 1/[1 + \exp[(V - V_{1/2})/k]]$ , where  $G$  is peak conductance,  $G_{\max}$  is maximal conductance,  $V_{1/2}$  is half-activation voltage, and  $k$  is a slope factor. Current steady-state inactivation curves were fitted with the following equation:  $I/I_{\max} = 1/[1 + \exp(-(V_m - V_{1/2\text{inact}})/k)]$ , where  $I/I_{\max}$  is the normalized maximum current,  $V_m$  is the conditioning prepulse,  $V_{1/2\text{inact}}$  is the voltage for half-inactivation, and  $k$  is a slope factor.

**Western blot analysis.** Total protein extracts from HEK293 cells were obtained using 200  $\mu$ l of lysis buffer (50 mM Tris-HCl, pH 8.0; 150 mM NaCl; 0.5 mM PMSF; 1% Triton X-100; and 1 $\times$  protease inhibitor mix (Roche Applied Science). After centrifugation, supernatants were collected for protein quantification by the Bradford assay (Bio-Rad). Aliquots of 60  $\mu$ g of total protein extracts were boiled in SDS sample buffer (50 mM Tris-HCl, pH 6.8; 2% SDS; 10% glycerol; 0.1% 2-mercaptoethanol; 0.001% bromophenol blue), electrophoresed on 8% SDS-polyacrylamide gels, and transferred to nitrocellulose membranes. After blocking with nonfat milk (5%) supplemented with 0.2% Tween 20, membranes were incubated for 1 h with the primary antibodies anti-Ca<sub>v</sub>3.2, anti-Cdk5, or anti-p35 (H-300, catalog #sc-25691; C-8, catalog #sc-173; and C-19, catalog #sc-820; respectively. Santa Cruz Biotechnology) at 1:1000 dilution in TBS-T with 5% nonfat milk, washed with TBS-T (10 mM Tris-HCl, 0.15 M NaCl, 0.05% Tween 20), and then incubated with goat anti-rabbit secondary antibody coupled to horseradish peroxidase for 1 h. Immunoblots were developed by using the ECL Western blotting analysis system (GE Healthcare Life Sciences) and were visualized with the Odyssey Fc Imaging System (LI-COR Biosciences). The densitometric quantification was performed using ImageJ software (NIH).

Total protein extracts from animal tissues were obtained as follows. Animals were killed by decapitation, and the DRG L5 and L6 were extracted and placed in 1.5 ml tubes containing lysis buffer (150 mM NaCl; 50 mM Tris-HCl, pH 7.5; 1% SDS; 0.5% sodium deoxycholate; 0.1% Triton X-100; 1 mM PMSF; and complete). Next, tissues were homogenized at 4°C and kept on ice for 20 min, then centrifuged for 10 min at -4°C at 14,000 rpm (16,464  $\times$  g). The supernatants containing the proteins were collected for quantification using the Bradford method. Denaturing electrophoresis in 10% polyacrylamide gels with SDS (i.e., SDS-PAGE) using 60  $\mu$ g of total proteins was then performed. Samples were heated at 95°C for 5 min and loaded onto gels. Subsequently, proteins were transferred to polyvinylidene membranes and blocked with 5% skimmed milk in PBS-0.05% Tween 20 (PBST), pH 7.4, for 1–2 h at

room temperature. Membranes were then washed with PBST and incubated with the mouse anti-Ca<sub>v</sub>3.2 (1:500 dilution), anti-Cdk5 (1:5000), anti-p35 (1:1000; Santa Cruz Biotechnology), and anti-β-actin (1:10,000; GeneTex), and incubated for 16 h at 4°C. Secondary horseradish peroxidase-conjugated antibodies (anti-rabbit, 1:10000; or anti-mouse, 1:5000) were used in conjunction with the chemiluminescence detection system. Signals were quantified as the optical density index by using the Image Studio 5.2 software (LI-COR Biosciences). The optical density index of each band was normalized to the optical density index of β-actin.

**Immunoprecipitation.** Protein extracts from DRG and transfected cells were solubilized in RIPA buffer (25 mM Tris-HCl, pH 7.6; 150 mM NaCl; 1% NP-40; 1% sodium deoxycholate; 0.1% SDS; 0.5 mM PMSF; and Complete 1×). For inputs, 60 μg of protein samples were boiled for 5 min in protein-loading buffer (1.7% SDS; 100 mM 2-mercaptoethanol; 5% glycerol; 58 mM Tris-Cl; and 0.002% bromophenol blue, pH 6.8). Each immunoprecipitation assay was performed with 1 mg of protein and 2.5 μg of anti-Cdk5, anti-Ca<sub>v</sub>3.2, or irrelevant (as isotype control) antibodies, allowing protein interaction overnight at 4°C. Next, the complexes were incubated with 20 μl of Invitrogen recombinant Protein G Agarose (Thermo Fisher Scientific). Immunoprecipitates were washed with a buffer containing 50 mM Tris-HCl, pH 8, 150 mM NaCl, 1 mM EDTA, 1% Triton X-100, 10% SDS, and 100 mM PMSF, followed by two PBS washes. Protein complexes were eluted in 30 μl of protein-loading buffer, resolved by 8% SDS-PAGE, and then immunoblotted with the anti-Ca<sub>v</sub>3.2, anti-Cdk5, or anti-phosphoserine antibodies (catalog #p5747, Sigma-Aldrich).

**Transient transfection.** HEK293 cells (catalog #CRL-1573, ATCC) were maintained in DMEM-HG cell culture medium, as mentioned previously. Gene transfer was performed using Invitrogen Lipofectamine Plus Reagent (Thermo Fisher Scientific). Briefly, for a 35 mm Petri dish, 1.6 μg of the plasmid cDNA encoding the human T-type Ca<sup>2+</sup> channel Ca<sub>v</sub>3.2α<sub>1</sub> subunit (GenBank accession #AF051946; Perez-Reyes et al., 1998), or its S561A or S1987A mutants, were premixed with 9 μl of Lipofectamine in 100 μl of serum-free medium, according to the manufacturer instructions, in the presence or absence of 1.5 μg of Cdk5 (NM\_007668.3) and 0.5 μg of p35 (U89527.1) plasmid constructs.

**Site-directed mutagenesis.** Multiple nucleotide sequences were aligned using the modified Clustal W algorithm of the Invitrogen Vector NTI 8 software package (Thermo Fisher Scientific). Phosphorylation site prediction was performed using the GPS 3.0 software (Group-based Prediction System, version 3.0), a state-of-the-art web-based software for prediction of phosphorylation (available at <http://gps.biocuckoo.org/>). The Ca<sub>v</sub>3.2 cDNA was cloned into the expression plasmid pcDNA3 and expressed under the control of the cytomegalovirus promoter. Two individual point mutations (S561A and S1987A) were introduced with ~40-mer synthetic oligonucleotides using the Quick-Change XL-mutagenesis kit (Stratagene). A third mutant included the mutation of both serine residues (S561 and S1987). All cDNA constructs were sequenced (PerkinElmer/Thermo Fisher Scientific).

**Plasma membrane protein extraction.** HEK293 cells stably expressing Ca<sub>v</sub>3.2 channels were transfected or not (control) with the cDNA encoding the Cdk5/p35 complex. After 48 h, the extraction of membrane proteins was performed using the Membrane Protein Extraction Kit (catalog #K268, BioVision) according to the manufacturer instructions. Briefly, cells were grown in 100 mm culture dishes and collected by centrifugation (700 × g, for 5 min), washed with cold PBS, resuspended, and homogenized. The homogenates were centrifuged at 700 × g for 10 min. Pellets containing the cell membrane proteins were mixed with 200 μl of the upper and lower phase solutions and centrifuged at 1000 × g for 5 min. The upper phase was transferred to a new tube, diluted in 5 volumes of double-distilled water, and centrifuged for 30 min. Supernatants were removed, and the pellets containing the membrane proteins were dissolved in 0.5% Triton X-100 in PBS. Proteins were then quantified using the Bradford method, separated by SDS-PAGE gel electrophoresis, and transferred to nitrocellulose membranes. For Ca<sub>v</sub>3.2 channel detection, the membranes were incubated with the anti-Ca<sub>v</sub>3.2 antibody (Santa Cruz Biotechnology), and the loading control protein was detected with an anti-Cadherin antibody (1:15,000 dilution; Thermo Fisher Scientific).

The quantification of the Ca<sub>v</sub>3.2 signal was normalized to Cadherin and expressed as arbitrary units.

**Induction and evaluation of mechanical allodynia.** Behavioral tests were performed using male Wistar rats (150–170 g). Animals were maintained with free access to food and water, in a controlled environment at 22°C and under a 12 h light/dark cycle. All experiments were performed in accordance with the guide on ethical guidelines for investigations of experimental pain in conscious animals (Zimmermann, 1983). In addition, all studies were approved by the Institutional Animal Care and Use Committee (Protocol 0198–16, Centre for Research and Advanced Studies, Mexico City, Mexico) and complied with the Official Mexican Standard (NOM-062-ZOO-1999).

Animals were anesthetized by intraperitoneal injection of a mixture of ketamine (50 mg/kg) and xylazine (10 mg/kg). After surgical preparation, the left spinal nerves L5 and L6 were exposed by removing the paraspinal muscles and ligated with a 6–0 silk suture in a region distal to the DRG (Kim and Chung, 1992). In the case of the sham-operated rats, the nerves were exposed but not ligated. To determine the presence of mechanical allodynia, the animals were kept in acrylic cages and allowed to habituate for 1 h, and subsequently von Frey filaments (Stoelting) were used to determine the threshold of removal (50% paw withdrawal threshold) of the hindlimb using the up-and-down method (Chaplan et al., 1994). On days 11–14 after surgery, animals are evaluated again with the von Frey filaments to corroborate the presence of mechanical allodynia. Briefly, the tests started with a filament of 2 g, in the middle of a series of 20 filaments with different rigidity or hardness, which was changed according to the response of the animal. The 50% withdrawal threshold was determined according to the following formula: 50% threshold (g) = (10<sup>x</sup> [Xf + kδ])/10,000, where Xf is the value of the last von Frey filament used (in logarithmic units); k is the correction factor based on the response patterns of a calibration table and the tabulated value based on the pattern of positive and negative responses; and δ denotes the average differences between stimuli in logarithmic units (Chaplan et al., 1994). The presence of allodynia is considered when the 50% withdrawal threshold of the limb is <4 g.

**Intrathecal drug administration.** Anesthetized animals were held securely with one hand on the iliac crests while a 25 gauge needle was inserted between the lumbar spinous processes 4 and 5 (Mestre et al., 1994). The needle enters the subarachnoid region perpendicularly producing an involuntary movement of the tail indicative of the appropriate insertion. Before the behavioral evaluation, animals were allowed to recover from anesthesia. Next, the Cdk5 inhibitor olomoucine (100 μM) was administered intrathecally to a group of rats. Another group of animals was given 0.025% DMSO as a control. This evaluation and administration protocol was performed on days 12, 13, and 14 after spinal nerve ligation (SNL).

**In vitro recordings of cAPs.** The spinal nerve–DRG–dorsal root (SN–DRG–DR) preparations were obtained from control (sham) and SNL rats 14 d after surgery. Animals were anesthetized and subjected to a laminectomy that allowed dissection and extraction of the DRG in continuity with the spinal nerves and the dorsal roots. Tissues were collected in Hartmann solution containing the following (in mM): 117 NaCl, 3.6 KCl, 2.5 NaHCO<sub>2</sub>, 1.2 MgCl<sub>2</sub>, 25 C<sub>6</sub>H<sub>12</sub>O<sub>6</sub>, and 1 CaCl<sub>2</sub> bubbled continuously with mixed gas consisting of 95% O<sub>2</sub> and 5% CO<sub>2</sub>. The recordings of the cAPs were obtained at room temperature (~22°C) by placing the SN–DRG–DR preparation into a recording chamber as follows. The distal end of the spinal nerve was suctioned with a glass electrode connected to an electrical stimulator of rectangular pulses, while the proximal end of the dorsal root was suctioned with a glass electrode connected to an AC amplifier. cAPs were evoked by stimulation of the distal end of the spinal nerves with 300-μs-duration current pulses and recorded at the central end with a gain × 1000 with DC-3 kHz filters. One hundred millisecond traces were digitized with a Digidata interface (Molecular Devices) at 50 kHz and stored in the hard disk of a computer for analysis. The cAPs threshold (T) was determined as the necessary current to evoke a cAP with an occurrence of 50%. Once the cAP recordings evoked at 1.5 × T were stable, we proceeded to stimulate at intensities of 1.5, 3, 10, 30, and 50 × T to obtain the cAPs from distinct primary afferent fibers. To obtain cAPs from synchronized C fibers a total length of ~12 mm was selected,

which included the spinal nerve, the DRG, and the dorsal root. For each stimulation intensity, 30 traces were recorded at a frequency of 0.2 Hz in the absence or the presence of olomoucine (100  $\mu$ M) and/or mibefradil (500 nM).

**Statistical analysis.** All data are presented as the mean  $\pm$  SEM. Data normality was initially determined using the Kolmogorov–Smirnov test. When data were normally distributed, the statistical significance of differences between two sets of averaged data was established according to the Student's *t* test. Likewise, ANOVA was also performed for multiple comparisons and Bonferroni's *post hoc* test was used for pairwise comparisons (Table 1). Experiments using antibodies were performed at least in triplicate; *n* refers to the number of animals or cells under each condition. Statistical significance is indicated by an asterisk. When data were not normally distributed, the statistical significance of differences was assessed using Kruskal–Wallis analyses followed by Dunn's *post hoc* tests for pairwise comparisons (Table 1). Statistical analysis was performed using SigmaPlot (version 12.3, SYSTAT) and GraphPad Prism version 7 (GraphPad Software).

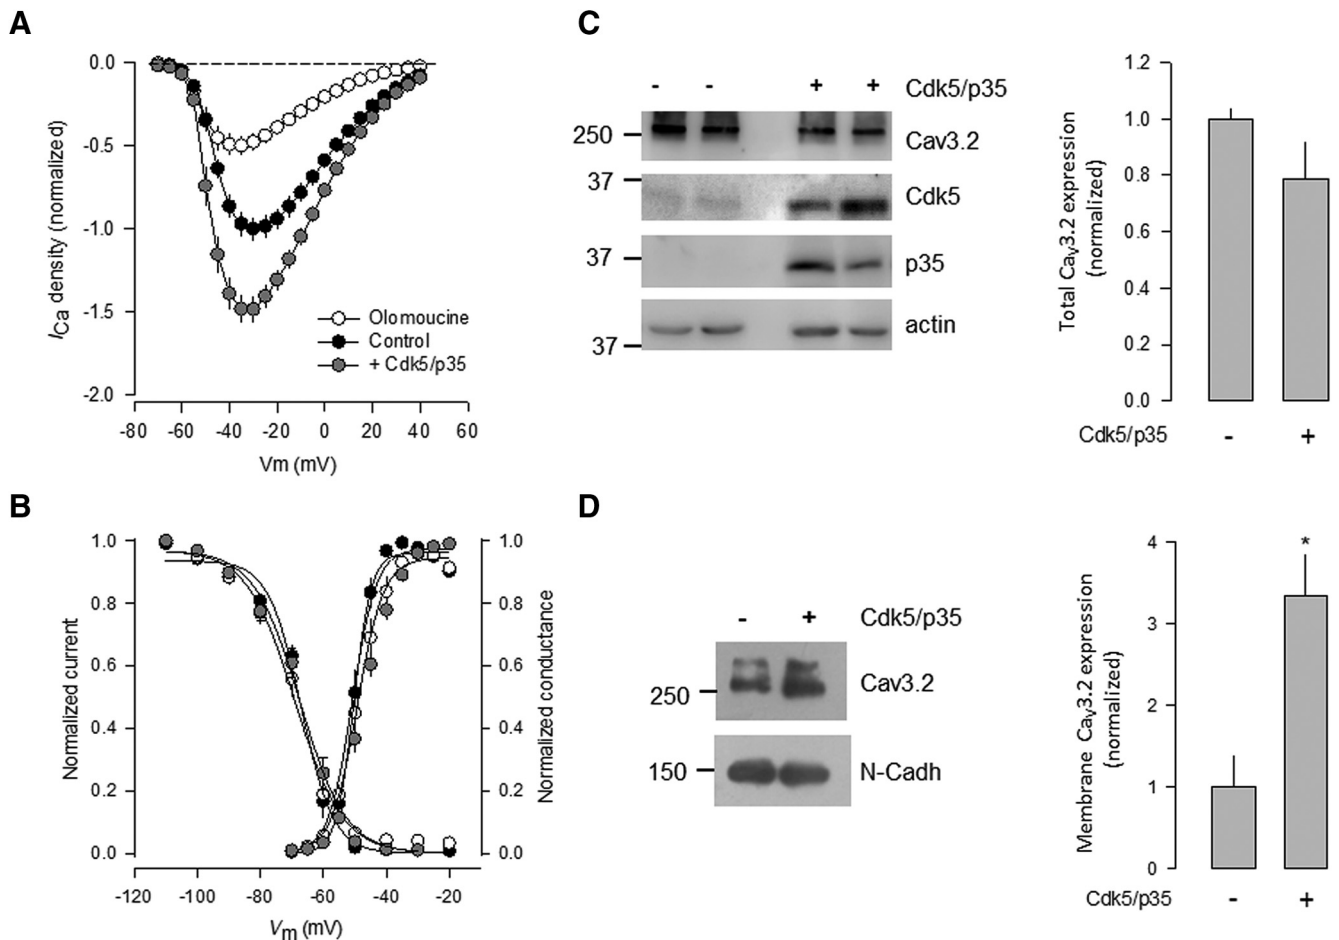

## Results

### Upregulation of Ca<sub>v</sub>3.2 current by Cdk5/p35 transfection

We first evaluated the functional consequences of the Cdk5/p35 complex on the activity of T-type Ca<sub>v</sub>3.2 channels, by whole-cell patch-clamp recordings performed in HEK293 cells stably expressing the channels, after transient transfection of Cdk5/p35. As shown in Figure 1A, current density through Ca<sub>v</sub>3.2 channels was significantly increased in the voltage range of  $-50$  to  $0$  mV, in the presence of the Cdk5/p35 complex components, compared with the control condition. Likewise, the presence of the Cdk5

inhibitor, olomoucine (100  $\mu$ M; 48 h), prevented the stimulatory effect of the kinase on the Ca<sub>v</sub>3.2 current density. This is consistent with our previous observation that the silencing of Cdk5 using specific siRNAs abrogates the effect of the kinase on the Ca<sub>v</sub>3.1 channels heterologously expressed in HEK293 cells (Calderón-Rivera et al., 2015). To investigate whether the Cdk5/p35 complex effect on the Ca<sub>v</sub>3.2 channels was mediated by alterations in channel gating, the voltage dependence of the currents was assessed next. A normalized conductance–voltage relationship was then generated for the control (GFP transfected) and Cdk5/p35-transfected cells (Fig. 1B). The results show that the half-maximal activation voltage ( $V_{1/2}$ ) in the control cells was approximately  $-44$  mV, which did not differ significantly from that of the Cdk5/p35-transfected cells (approximately  $-47$  mV). The slope factors (*k*) for the Boltzmann fits were also similar.

Likewise, the properties of current inactivation at steady state were determined using 1 s conditioning prepulses ranging from  $-110$  to  $-20$  mV in 10 mV voltage steps, followed by a 140 ms step depolarization to  $-30$  mV. The normalized current amplitudes were plotted against its corresponding potential and fitted with Boltzmann equations. The results show that the voltage dependence of inactivation was similar in the currents recorded from control cells and cells expressing Cdk5/p35 (Fig. 1B). For control cells, the  $V_{1/2}$  was  $-71$  mV, which did not differ significantly from that of Cdk5/p35-transfected cells ( $-67.5$  mV). Given that the slope factors were also unaffected, it is concluded that the presence of the kinase and its activator augment the

**Figure 1.** The cotransfection of Cdk5 and p35 regulates the expression of recombinant Ca<sub>v</sub>3.2 channels in HEK293 cells. **A**, Averaged and normalized Ca<sub>2+</sub> current ( $I_{Ca}$ )-voltage relationships in HEK293 cells stably expressing Ca<sub>v</sub>3.2 channels in the control condition or after transient transfection of the Cdk5/p35 complex, as well as after treatment with the kinase inhibitor olomoucine (100  $\mu$ M) for 48 h ( $n = 18$ –35 recorded cells). **B**, Comparison of steady-state inactivation and activation curves for Ca<sub>v</sub>3.2 channels as in **A** ( $n = 15$ –26). Curves were fitted with Boltzmann equations. A two-pulse protocol was used to estimate the voltage dependence of inactivation. The channel activation curve was estimated by measuring peak current during different test steps from a  $V_h$  value of  $-80$  mV. The current value at each potential was divided by the driving force for Ca<sup>2+</sup> ions. **C**, Western blot analysis showing the expression of Ca<sub>v</sub>3.2, Cdk5, and p35 in total lysates from HEK293 cells in the presence and absence of Cdk5/p35, as indicated (left).  $\beta$ -actin was used as a loading control. Right, The bar chart summarizes the results of four independent experiments. The differences observed were not statistically significant according to the Student's *t* test (Table 1). In addition, the power of the performed test (0.252) was below the desired power of 0.800. **D**, Western blot of HEK293 membrane protein lysates obtained with anti-Ca<sub>v</sub>3.2 antibodies in the presence and the absence of Cdk5/p35, as indicated (right). The apparent molecular size markers are shown on the left. N-Cadherin (N-Cadh) was used as the loading control. The bar chart on the right summarizes the results of four independent experiments, and the asterisk denotes a significant difference from the control condition (Table 1).

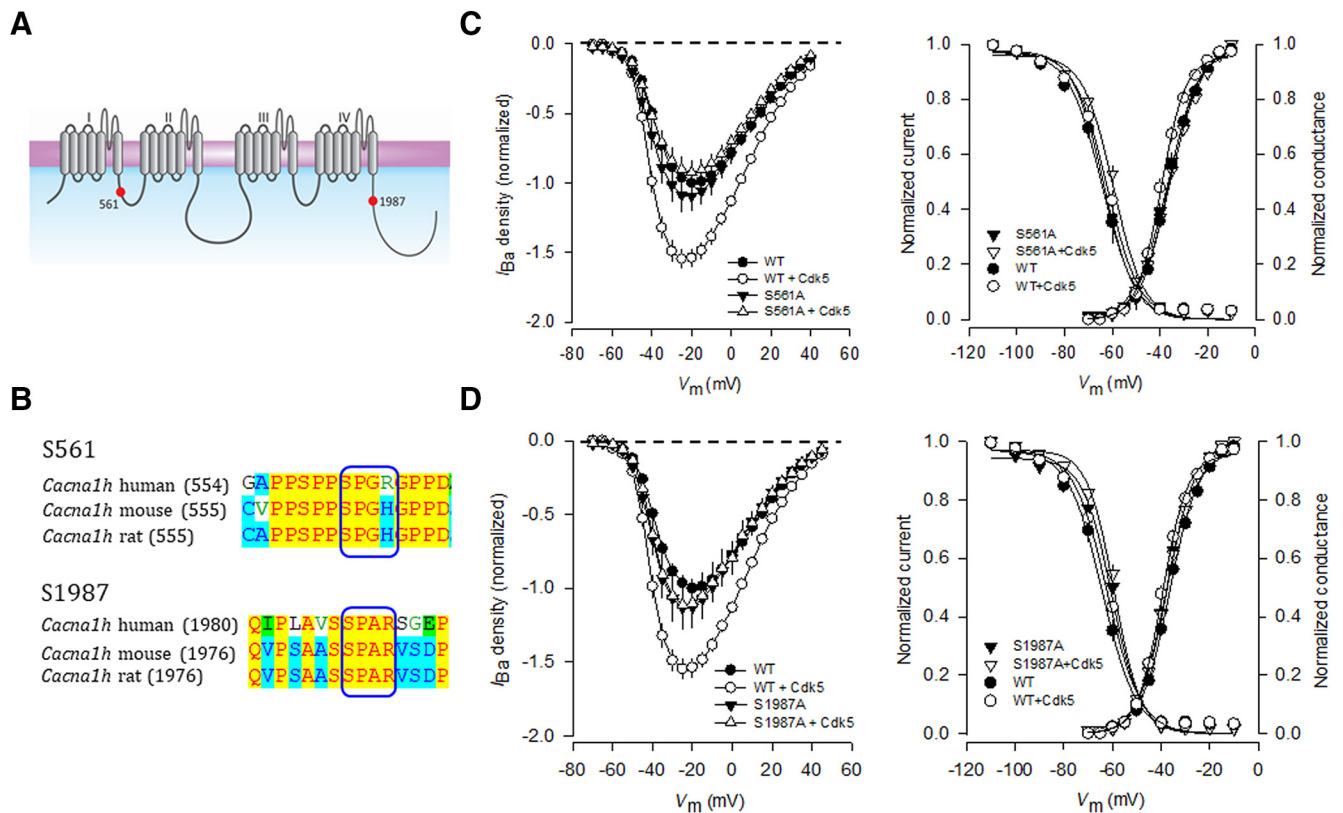

density of the Ca<sub>v</sub>3.2 channel currents with no significant effects on the gating of the channels.

#### Cdk5/p35 transfection increases the membrane expression of recombinant Ca<sub>v</sub>3.2 channels

To investigate whether the current density increase observed in the functional studies was related to an augmentation in Ca<sub>v</sub>3.2 protein expression, we analyzed the total protein expression in whole-cell lysates obtained from HEK293 cells. The components of the Cdk5/p35 complex were transfected in the HEK293 cells stably expressing Ca<sub>v</sub>3.2 channels, and the relative expression of the channel protein was determined by Western blotting. To this end, specific anti-Ca<sub>v</sub>3.2 antibodies were used, and the channel signal was compared with the loading controls using anti-actin antibodies (Fig. 1C). The Ca<sub>v</sub>3.2 channel protein appeared as a >250 kDa band whose expression was slightly decreased, in the presence of Cdk5/p35 (Fig. 1C, right). The differences observed were not statistically significant (Table 1), and the power of the statistical test performed was below the desired value. This result

suggests that the increase in current density after Cdk5/p35 expression may not be attributable to higher levels of total channel protein expression. It is worth mentioning that in untransfected HEK293 cells we found a  $\sim 35$  kDa protein band using the anti-Cdk5 antibody, suggesting that Cdk5 is endogenously expressed in this cell line (Fig. 1C, left).

The previous electrophysiological results suggested that the upregulation of the current caused by Cdk5/p35 could be related to an increase in the number of channels located at the plasma membrane. To test this, we next performed experiments in which plasma membrane proteins were isolated from cells stably expressing the Ca<sub>v</sub>3.2 channel alone or transfected with the Cdk5/p35 complex. As shown in Figure 1D, the densitometric analysis showed that the expression of Cdk5/p35 resulted in higher levels of the Ca<sub>v</sub>3.2 channel protein at the plasma membrane fraction compared with the control condition. Together, these data suggest that the Cdk5/p35 complex may play a relevant role in favoring the localization of the channels at the cell membrane, without changing significantly their total expression.

**Figure 2.** The S561A and S1987A mutations prevent the Cdk5/p35-mediated regulation on Ca<sub>v</sub>3.2 channel activity. **A**, The Ca<sub>v</sub>3.2α<sub>1</sub> subunit is a monomer consisting of four homologous repeated domains (I–IV) with six transmembrane segments (S1–S6). The S4 in each repeated domain has positively charged amino acids and represents the voltage sensor. The pore region is defined by the loop between S5 and S6. The mutations generated in this study are denoted as small red circles. **B**, Sequence alignment of regions in the Ca<sub>v</sub>3.2α<sub>1</sub> protein from distinct species showing the consensus phosphorylation site for Cdk5. **C**, Average normalized Ba<sup>2+</sup> current (*I*<sub>Ba</sub>) densities as a function of voltage (*I*–*V* curves) in HEK293 cells transiently expressing the wild-type or the S561A mutant Ca<sub>v</sub>3.2α<sub>1</sub> subunits obtained in the presence or absence of Cdk5 (left). Right, Comparison of the corresponding average normalized activation and steady-state inactivation curves (*n* = 11–35). **D**, Average normalized *I*–*V* curves in HEK293 cells expressing the wild-type or the S1987A mutant Ca<sub>v</sub>3.2α<sub>1</sub> subunits obtained in the presence or absence of Cdk5. Right, Corresponding average normalized activation and steady-state inactivation curves (*n* = 11–35).

### S561 and S1987 mutation prevents the Cdk5/p35-mediated regulation of the channels

Recently, multiple phosphorylatable residues for the human Ca<sub>v</sub>3.2 channel have been reported (Blesneac et al., 2015). However, for most of these phosphorylation sites, the kinase or their functional effects have not been described. Given that Cdk5 is able to regulate the currents through Ca<sub>v</sub>3.2 channels, we searched for possible amino acids in the Ca<sub>v</sub>3.2 protein that could be phosphorylatable by the kinase. Initial *in silico* analysis of the human Ca<sub>v</sub>3.2 channel using a computational prediction software (available at <http://gps.biocuckoo.org/online.php>), showed 15 potential phosphorylation sites for Cdk5. The consensus sequence of phosphorylation by Cdk5 has been reported to be S or T/P/X/(H, R or K): in the first position the serine or threonine target to be phosphorylated (p), followed by a proline, any amino acid in the third position and finally a histidine, arginine, or lysine residue. According to this, our search was reduced to only two serine candidates located at positions 561 and 1987, which coincidentally had the highest scores and were conserved among human, rat, and mouse (Figs. 2A,B). Therefore, these amino acid residues were selected for further mutagenesis analyses.

We first mutated S561 and S1987 residues individually to alanine, and the mutant channels were heterologously expressed in HEK293 cells and analyzed by patch-clamp electrophysiology. As previously shown, the transient transfection of Cdk5/p35 increased the wild-type Ca<sub>v</sub>3.2 channel current density, without affecting the activation or inactivation properties of the channels.

In sharp contrast, the presence of the mutations prevented the upregulation of the currents caused by Cdk5/p35 (Figs. 2C,D, left panels). The activation and inactivation curves were also similar in both conditions (Fig. 2C,D, right panels). These results support the idea that the serine residues at positions 561 and 1987 in Ca<sub>v</sub>3.2 are required for the Cdk5/p35-mediated regulation.

The effect of Cdk5/p35 on Ca<sub>v</sub>3.2 channels bearing an S561A/S1987A double mutation was then investigated. To this end, we first performed whole-cell patch-clamp experiments on HEK293 cells expressing the wild-type Ca<sub>v</sub>3.2 channels and the double mutant. Figure 3A compares the amplitude of the currents elicited by a depolarization step from a holding potential (*V*<sub>h</sub>) of –80 mV to a test potential of –30 mV obtained in the presence and the absence of Cdk5/p35. The amplitude of the currents through wild-type channels was increased after Cdk5/p35 coexpression. In comparison, no modification of the currents through channels harboring the double mutation was observed in the presence of the kinase and its activator (Fig. 3A). In consequence, the current density–voltage relationships obtained in the absence of Cdk5/p35 were similar to those observed in the wild-type channel currents but, as expected, the transient transfection of the Cdk5/p35 complex did not stimulate the current as observed for the wild-type channels (Fig. 3B). The voltage dependence of activation and inactivation remained unchanged, as occurred with the single S561A and S1987A mutations (Fig. 3C).

We next sought to determine whether the loss of the Cdk5/p35-mediated functional regulation in the S561A/S1987A mu-

**Figure 3.** The double S561A/S1987A mutant is insensitive to the Cdk5/p35-mediated regulation. **A**, Representative superimposed Ba<sup>2+</sup> current ( $I_{Ba}$ ) traces recorded in HEK293 cells transiently transfected the wild-type or the double mutant (S561A/S1987A; DM) Ca<sub>v</sub>3.2 $\alpha$ 1 subunits. Currents were evoked by applying voltage steps to  $-30$  mV from a  $V_h$  of  $-80$  mV. **B**, Average normalized  $I$ - $V$  curves in HEK293 cells expressing the wild-type or the Ca<sub>v</sub>3.2 $\alpha$ 1 DM subunits obtained in the presence or absence of Cdk5 as in **A** ( $n = 18$ – $35$  recorded cells). **C**, Average normalized activation and steady-state inactivation curves as a function of membrane voltage obtained in transfected cells as in **B** ( $n = 18$ – $35$ ). Normalized activation and inactivation curves were fit to Boltzmann functions. **D**, **E**, Cdk5/p35 regulates the levels of Ca<sub>v</sub>3.2 at the plasma membrane but not the DM mutant channel. **D**, Western blot analysis of the Ca<sub>v</sub>3.2 $\alpha$ 1 DM channel protein expression at the membrane in HEK293 cells in the absence or presence of Cdk5/p35 were separated by SDS-PAGE, and the bands were normalized to p-Cadherin ( $n = 6$  independent experiments). **E**, Immunodetection of the Ca<sub>v</sub>3.2 $\alpha$ 1 WT or DM membrane proteins plus Cdk5/p35. The signal for the Ca<sub>v</sub>3.2 channel was normalized to p-Cadh, used as loading control, and detected by chemiluminescence, as described in Materials and Methods. The bar charts at the right summarize the results of six independent experiments, and the asterisk denotes a significant difference from the control condition (Table 1).

tant channels was associated with less channel expression at the cell membrane. To this end, the relative expression of the Ca<sub>v</sub>3.2 wild-type and the mutant construct were quantified and normalized to p-Cadherin. Figure 3, *D* and *E*, shows that the relative expression of the S561A/S1987A mutant channels in cell membrane extracts from transfected HEK293 cells was similar in the absence and the presence of the Cdk5/p35 complex (Fig. 3*D*, right). However, the proportion of wild-type channels was approximately twofold higher than the S561A/S1987A mutant channels in the presence of Cdk5/p35 (Fig. 3*E*, right).

The above-described results suggested that Cdk5/p35 modulates the Ca<sub>v</sub>3.2 channels through phosphorylation of serine residues at positions 561 and 1987. Therefore, we next decided to investigate in more detail the interaction between the kinase and the Ca<sub>v</sub>3.2 channels using immunoprecipitation assays. Figure 4, top, shows that the use of a Cdk5-specific antibody resulted in the immunoprecipitation of a  $>250$  kDa band, the expected size of the Ca<sub>v</sub>3.2 channel protein (detected using a Ca<sub>v</sub>3.2 antibody). To investigate whether the presence of the S561A and S1987A mutations in the Ca<sub>v</sub>3.2 channel may alter the interaction with Cdk5, we transfected HEK293 cells with the cDNAs encoding the mutant channels and performed the immunoprecipitation assays in the same experimental conditions. Figure 4*A*, middle and bottom, shows that the interaction of the kinase with the Ca<sub>v</sub>3.2 proteins occurs with both the wild-type and the mutant channels, suggesting that the kinase could be interacting with other sites in the channel protein; however, the intensity of the immunosignal was decreased in the presence of the Cdk5 inhibitor olomoucine (Fig. 4*A*, middle) or the mutations (Fig. 4*A*, bottom). Here it is

worth noting that these results show an additive reduction of interaction using the double mutant, but the functional studies show a full effect with only one mutation. The reason for this discrepancy is not presently known, however, it could be related to the fact that the mutation of only one of the serine residues is sufficient to induce a conformational change in the channel protein that abrogates the functional effect of the phosphorylation event. On the other hand, the mutation of two serine residues, in addition to affect the phosphorylation process, could be causing a greater disruption in the physical interaction between the kinase and the channels.

We next studied the phosphorylation of the wild-type channel and its mutants using anti-phosphoserine antibodies in the absence and the presence of olomoucine. Figure 4, *B* and *C*, shows that, in the presence of the Cdk5 inhibitor or the mutations in the serine residues, the phosphorylation of the channel was significantly decreased.

The interaction between Cdk5 and the Ca<sub>v</sub>3.2 channels was also observed in immunoprecipitation assays using cell lysates from DRG. As can be seen in Figure 5*A*, the immunoprecipitation assay using an anti-Cdk5 antibody and the subsequent analysis by Western blot revealed the presence of a  $>250$  kDa band, the expected size for the Ca<sub>v</sub>3.2 channel protein. On the other hand, the reciprocal experimental maneuver, that is, the immunoprecipitation using an anti-Ca<sub>v</sub>3.2 antibody and the subsequent analysis by Western blot, resulted in the identification of a band of a  $\sim 35$  kDa, the estimated size of the kinase. We then evaluated the possible functional consequences of the Cdk5/p35-mediated phosphorylation on the Ca<sub>v</sub> channels in the DRG neurons by

comparing the current densities in the absence and the presence of olomoucine. Figure 5B shows superimposed representative traces of the total currents through Ca<sub>v</sub> channels in DRG neurons in the presence and the absence of the Cdk5 inhibitor. Interestingly, the presence of olomoucine significantly reduced Ca<sub>v</sub> current density in the DRG neurons (Fig. 5C). It is worth recalling that the DRG neurons express both HVA and low voltage-activated (LVA) channels; therefore, we next investigated whether the effects of olomoucine were mediated by its action on the LVA channels (T-type or Ca<sub>v</sub>3). To separate the total current into its two components, a standard experimental maneuver was used, which consisted in applying two 100 ms depolarizing steps to 0 mV from a V<sub>h</sub> of −80 mV separated by a 10 ms interpulse interval. The two components of the total currents are activated during the first step; however, the LVA channels inactivate at the end of this pulse. As a consequence, the second depolarizing step to 0 mV activates only the HVA component of the current. By subtracting the currents obtained in response to the second pulse from those obtained with the application of the first pulse, the magnitude of the LVA component could be estimated. When comparing the results of this analysis, we found that olomoucine caused a significant decrease (of ~20%) in the density of the LVA currents recorded in the DRG neurons, suggesting that the kinase inhibitor was acting by preventing the phosphorylation of the LVA (Ca<sub>v</sub>3) channels (Fig. 5D).

#### Effect of the spinal nerve ligation on the expression and localization of Cav3.2

Given that diverse types of neuronal ion channels, including Ca<sub>v</sub>3.2, are important in the development of neuropathic pain, and that SNL induces mechanical allodynia in animal models, we next investigated the effect of SNL on the expression of the proteins of interest using specific antibodies. First, when studying the expression of the Ca<sub>v</sub>3.2 channel in the DRG of animals in the sham-operated and the SNL group, a band of >250 kDa was detected, which corresponds to the expected molecular weight of the channel protein (Fig. 6A,B). In these initial assays, SNL did not induce significant changes in the expression of the Ca<sub>v</sub>3.2 channels 14 d after nerve ligation (Fig. 6A), which disagrees with recent studies reporting an increase in the expression of these channels after injury or spinal nerve ligation (Shiue et al., 2016; Liu et al., 2019). Nevertheless, it is worth noting here that these results corresponded to what was observed from total cell lysates made from a preparation that included the spinal nerve, the DRG, and the dorsal root (not from the plasma membrane fraction only).

However, when the lysates were obtained from the nerves, the ganglia, or the dorsal roots separately, a differential distribution of the channel proteins was observed (Fig. 6B). In particular, a drastic decrease in Ca<sub>v</sub>3.2 expression was observed in the spinal

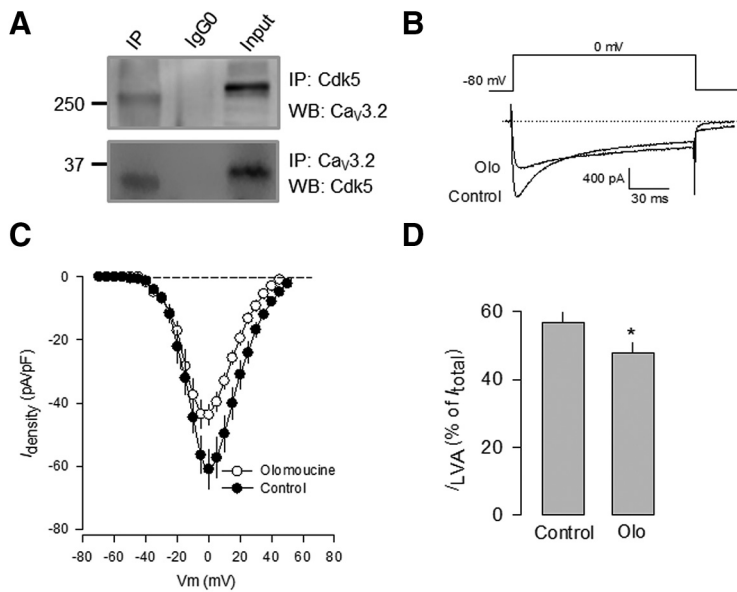

**Figure 4.** Cdk5 associates with the wild-type Ca<sub>v</sub>3.2 channel and its mutants in total lysates of HEK293 cells. **A**, Top, Cell lysates prepared from HEK293 transiently expressing Ca<sub>v</sub>3.2 channels were immunoprecipitated with Cdk5-specific antibodies. Immunoprecipitates were analyzed by SDS-PAGE and immunoblotted with anti-Ca<sub>v</sub>3.2 antibodies as indicated. Control IgG does not immunoprecipitate the channel Ca<sub>v</sub>3.2 $\alpha$ 1 protein. Middle, Immunoprecipitation of the Ca<sub>v</sub>3.2 channels from lysates of HEK293 cells expressing the wild-type or the S561A/S1987A double mutant (DM) channels in the presence or absence of the Cdk5 inhibitor olomoucine (Olo), using anti-Cdk5 antibodies. Bottom, Lysates from HEK293 cells expressing wild-type, S561A, S1987A, or DM Ca<sub>v</sub>3.2 channels were immunoprecipitated with anti-Cdk5 antibodies. Data are representative of three independent experiments. **B**, Cdk5 phosphorylates the Ca<sub>v</sub>3.2 channel expressed in HEK293 cells. Cell lysates prepared from HEK293 coexpressing Cdk5 and the wild-type or the DM Ca<sub>v</sub>3.2 channels were immunoprecipitated with Ca<sub>v</sub>3.2-specific antibodies in the presence or absence of Olo. Immunoprecipitates were analyzed by SDS-PAGE and immunoblotted with anti-phosphoserine (pSer) or anti-Ca<sub>v</sub>3.2 antibodies, as indicated. **C**, Bar chart summarizing the results of three independent experiments; the asterisk denotes a significant difference from the control condition (Table 1). IP, Immunoprecipitation; WB, Western blot.

nerves of animals subjected to SNL compared with sham-operated controls, and a significant increase (~2.5-fold) in the Ca<sub>v</sub>3.2 expression in the DRG after SNL was also observed. Together, these data suggest that there is an accumulation of Ca<sub>v</sub>3.2 channels in the DRG, as a result of a decrease in the channels in the spinal nerves (Chen et al., 2018; Liu et al., 2019).

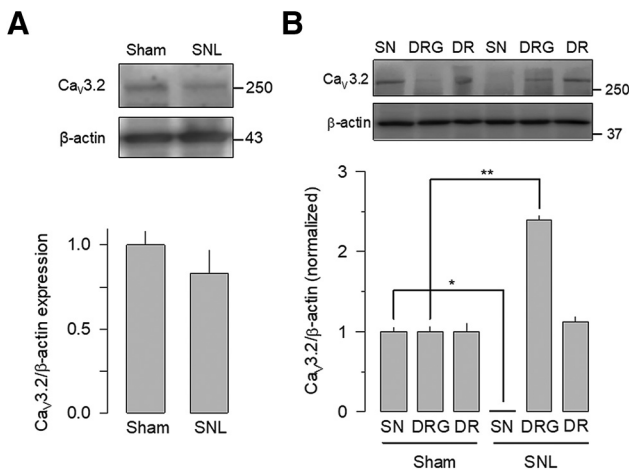

Likewise, in the case of Cdk5, an ~33 kDa band was observed in both sham-operated and animals with the nerve ligation. Figure 7A shows that ligation of the spinal nerves L5-L6 increased the expression of the kinase 14 d after nerve injury compared with what was observed in sham-operated animals. As for Ca<sub>v</sub>3.2, these initial results were obtained from total cell lysates that included the spinal nerves, the DRG, and the dorsal roots. When the lysates were obtained from the different anatomical regions separately, a significant increase in the expression of Cdk5 was observed in the DRG, but no apparent changes were noted in the spinal nerves or the dorsal roots (Fig. 7B).

In the case of the Cdk5 activators, p35 and p25, bands of ~35 and ~25 kDa corresponding to the molecular weight of these proteins were detected. Figure 8A shows that nerve injury had a dual regulation on the expression of p35 and p25 after 14 d of surgery. Hence, the expression of p25 increased significantly with respect to the control, while the expression of p35 decreased in parallel. Likewise, Figure 8, B and C, shows that the expression of p35 and p25 was also affected differentially when the anatomical regions were analyzed separately. While a decrease in the p35 expression was observed in the spinal nerves of animals subjected

**Figure 5.** Cdk5 regulates the Ca<sub>v</sub> channel currents in DRG neurons. **A**, Immunoprecipitation of Ca<sub>v</sub>3.2 channels and Cdk5 in the DRG. Top, Western blot (WB) of the immunoprecipitation (IP) of the Ca<sub>v</sub>3.2 channels using Cdk5 or control (IgG) antibodies. Bottom, Reciprocal immunoprecipitation experiment for Cdk5. The results are representative of three independent determinations. **B**, Superimposed current traces recorded in DRG neurons in the absence and the presence of the Cdk5 inhibitor olomoucine. Currents were evoked by applying voltage steps to 0 mV from a V<sub>h</sub> of  $-80$  mV. **C**, Average normalized  $I_{\text{density}}-V$  curves in DRG neurons obtained in the presence or absence of olomoucine as in **B** ( $n = 13$  recorded cells). For these electrophysiological recordings, only small cells were used (Scroggs and Fox, 1992). The  $C_m$  values varied from 22.2 to 23.4 pF, and the diameter of the cells ranged from 15.6 to 17.5  $\mu\text{m}$  in control and olomoucine-treated cells, respectively. **D**, Comparison of the isolated LVA (Ca<sub>v</sub>3) channel current component in the presence or absence of olomoucine. The asterisk denotes a significant difference from the control condition (Table 1).

**Figure 6.** SNL increases the relative expression of Ca<sub>v</sub>3.2 in the DRG. **A**, Top, Comparative Western blot analysis of Ca<sub>v</sub>3.2 protein expression in sham-operated animals and rats with allodynia induced by ligation of the spinal nerves L5–L6. Channel proteins were detected in cell lysates from DRG L5–L6 14 d after SNL using anti-Ca<sub>v</sub>3.2 antibodies. Bottom, Corresponding protein band signal intensities of channel proteins normalized to  $\beta$ -actin levels to obtain the relative expression of the Ca<sub>v</sub>3.2 $\alpha_1$  subunit. The results are representative of three independent experiments. **B**, Top, Comparative Western blot analysis of Ca<sub>v</sub>3.2 protein expression in sham-operated animals and rats with mechanical allodynia induced by the ligation of the spinal nerves, in lysates from the spinal nerve SN, the DRG, and the DR. Channel proteins were detected in lysates from L5–L6 14 d after SNL using anti-Ca<sub>v</sub>3.2 antibodies. Bottom, Corresponding protein band signal intensities of channel proteins normalized to  $\beta$ -actin levels to obtain the relative expression of the Ca<sub>v</sub>3.2 $\alpha_1$  subunit. The bar charts summarize the results of at least three independent experiments. Two-way ANOVA was performed for multiple comparisons followed by Bonferroni's tests for pairwise comparisons ( $*p = 0.012$ ,  $**p = 0.002$ ; Table 1).

to SNL compared with sham-operated controls, a significant increase (of  $\sim 20\%$ ) in the expression of this Cdk5 activator was observed in the DRG and the dorsal roots after SNL (Fig. 8B). In the case of p25, a significant increase ( $\sim 60\%$ ) was observed in the DRG (Fig. 8C), and no significant changes were noted in the rest of the regions analyzed.

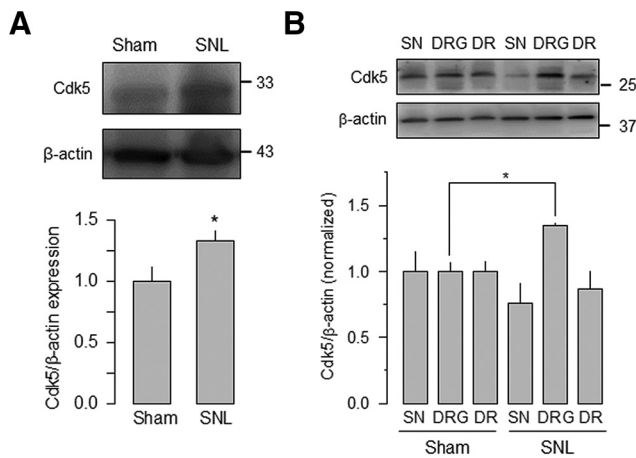

### Effect of the SNL and Ca<sup>2+</sup> channel blockers on the cAPs recorded in sensory C fibers

Given that the expression of both T-type channels and Cdk5 was altered in SNL animals with allodynia induced by SNL, we next sought to determine whether the increase in the functional expression of the channels induced by Cdk5-mediated phosphorylation might produce changes in cAPs of nociceptive afferent fibers in SNL animals. In an initial series of experiments, the animal model used was validated by assessing the withdrawal of the limb in response to stimulation with von Frey filaments, and the effect of the nerve ligation on the development of mechanical allodynia on days 1, 3, 7, and 14 was evaluated. Hence, stimulation on the plantar surface of the left hindlimb (ipsilateral) of the control (naive) group animals produced a 50% paw withdrawal

threshold of  $\sim 14$  g that was maintained throughout the evaluation period (14 d). Likewise, in sham-operated animals, the ipsilateral paw withdrawal threshold did not change significantly. In sharp contrast, the ligation of the spinal nerves decreased this withdrawal threshold (to  $< 4$  g) in the ipsilateral limb in response to stimulation with von Frey filaments (Fig. 9A).

We then studied the potential role of T-type channels on the excitability of the sensory nerve fibers. To this end, the cAPs evoked by stimulation of the spinal nerve L5 was recorded in the corresponding dorsal root in animals with allodynia induced by SNL (Fig. 9B). The cAPs recorded in the nerves of animals with surgically induced mechanical allodynia showed a smaller area under the curve (AUC;  $\sim 78\%$ ), with respect to those recorded in the control condition after peripheral nerve stimulation at  $3 \times T$ , where most of the primary afferent fast-conducting (proprioceptive) fibers are activated. In contrast, the AUC of cAPs recorded in sensory C-type (nociceptive) fibers, obtained by stimulation at  $50 \times T$ , were significantly increased (approximately twofold) with respect to the sham-operated rats (compare the corresponding traces in Fig. 9C,D).

Next, the possible contribution of different Ca<sub>v</sub> channels to the cAP of the sensory C-type fibers was investigated using mibefradil (500 nM) and  $\omega$ -conotoxin (Ctx)-GVIA (250 nM), which are antagonists of T- and N-type channels, respectively. Interestingly, mibefradil significantly reduced ( $\sim 30\%$ ) the AUC of cAPs in the nerves from animals with experimentally induced allodynia (Fig. 9D), while in the nerves of the sham-operated animals (Fig. 9C) the effect was a little smaller ( $\sim 25\%$ ). On the other hand, the sequential addition of the N-type channel blocker resulted in a larger reduction ( $\sim 50\%$ ) of the AUC of the cAPs in the recordings obtained from both the SNL and sham-operated ani-

**Figure 7.** SNL increases the relative expression of Cdk5 in the DRG. **A**, Top, Comparative Western blot analysis of Cdk5 expression in sham-operated animals and animals with mechanical allodynia induced by the ligation of the spinal nerves L5–L6. Cdk5 was detected in cell lysates from DRG L5–L6 14 d after SNL using specific antibodies ( $n = 3$  independent experiments).  $\beta$ -actin was used as a loading control. The asterisk denotes a significant difference from the control condition (Table 1). **B**, Top, Comparative Western blot analysis of Cdk5 protein expression in sham-operated animals and rats with mechanical allodynia induced by the ligation of the spinal nerves L5–L6, in lysates from the spinal nerve SN, the DRG, and the DR. Cdk5 was detected in lysates from L5–L6 (**B**) 14 d after SNL using specific antibodies. Bottom, Corresponding protein band signal intensities of Cdk5 normalized to  $\beta$ -actin levels to obtain the relative expression of the kinase. The bar charts summarize the results of three independent experiments, and the asterisks denote significant differences (Table 1).

mals (Fig. 9E,F). Here, it is worth mentioning that mibefradil blocks T-type channel activity with an IC<sub>50</sub> of ~300 nM, and that it has been shown to be >10-fold selective on T-type than on HVA channels (Todorovic et al., 2002). In addition, the drug is ~3.5-fold more selective for the T-type channels than for other ion channels, including Na<sup>+</sup> and delayed rectifier K<sup>+</sup> channels (Perchenet and Clément-Chomienne, 2000; Strege et al., 2005).

### Effects of olomoucine on the cAP recorded from sensory C fibers

We next investigated the role of the Cdk5-mediated regulation of the Ca<sub>v</sub>3.2 channels in the surgically induced mechanical allodynia using olomoucine. To this end, we first evaluated the presence of allodynia in the sham-operated and the SNL animals in the absence and presence of the Cdk5 inhibitor. Figure 10, A and B, shows that chronic intrathecal administration of the drug in animals subjected to SNL partially reversed the decrease in the paw withdrawal threshold that usually occurs after surgery, during 3 consecutive days to drug administration.

We also investigated whether the changes observed in mechanical allodynia after the intrathecal administration of olomoucine were related to the Cdk5 ability to affect the functional expression of the Ca<sub>v</sub>3.2 channels in primary afferent fibers. The results of these experiments indicated that in the SN–DRG–DR preparation, the kinase blocker decreased the AUC of the cAPs recorded in nerves from SNL animals (~31%), while in nerves from sham-operated animals this effect was significantly smaller (Fig. 10C). Likewise, we investigated whether the modification in the cAPs caused by olomoucine was related to a possible reduction in the stimulatory actions of Cdk5 on Ca<sub>v</sub>3.2 channel activity. To this end, cAPs evoked by stimulation of the spinal nerves and recorded in the dorsal roots in sham-operated rats and in animals with SNL, were recorded in the presence of the T-channel blocker mibefradil alone or in combination with olo-

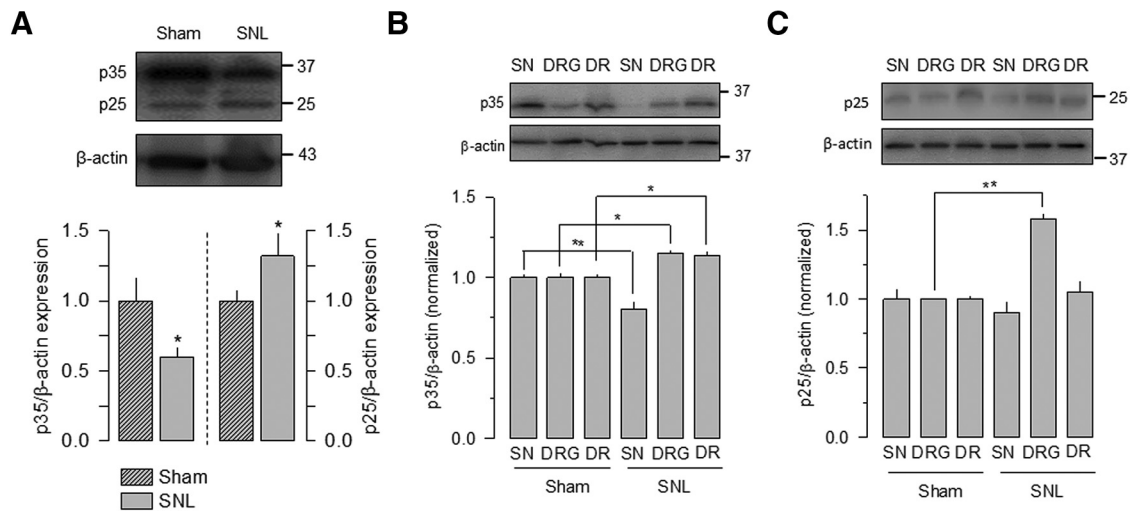

mooucine. The results of this analysis showed that mibefradil caused a decrease in the amplitude of the C component of the cAPs (of ~20%) in both experimental groups, while the combined administration of mibefradil and olomoucine had no additive effects (Fig. 10D,E). Therefore, the T-type channel antagonist had an occlusive effect on the inhibition caused by Cdk5, suggesting that both compounds share a convergent mechanism of action.

### Discussion

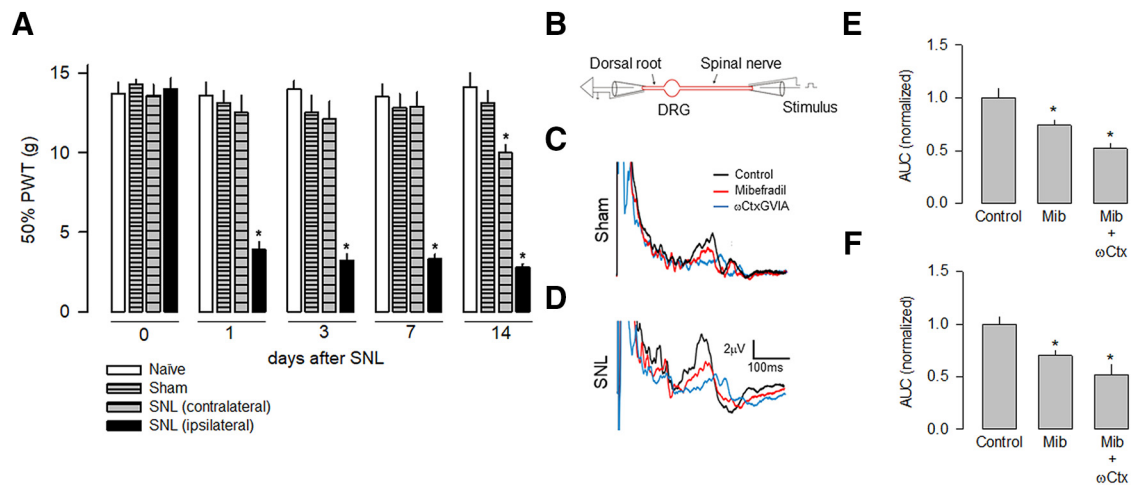

The biophysical properties of the T-type Ca<sub>v</sub> channels allow them to regulate neuronal excitability and contribute to the generation of subthreshold membrane potential oscillations that lead to Na<sup>+</sup>-dependent AP firing (Chemin et al., 2002; Cain and Snutch, 2010; Canto-Bustos et al., 2014; Lambert et al., 2014). These channels are expressed in peripheral sensory neurons, where they participate in nociceptive transmission and pain processing (Nelson et al., 2006; Bourinet et al., 2014, 2016; Carbone et al., 2014). Accordingly, the use of T-channel blockers alleviate the carrageenan-induced mechanical hyperalgesia (Watanabe et al., 2015), and the knockdown of Ca<sub>v</sub>3.2 channels restores normal paw withdrawal thresholds for tactile stimuli in an animal model of chronic pain induced by peripheral nerve constriction (Bourinet et al., 2005). Here, our studies on the contribution of the T-type Ca<sub>v</sub> channels to the excitability of sensory nerve fibers show that the cAPs evoked by stimulation of the spinal nerves and recorded in the corresponding dorsal root in animals with SNL (L5–L6), induces a significant increase in the C component compared with controls. We hypothesized that this observation might be explained by an increase in the functional activity of T-type Ca<sub>v</sub>3.2 channels class caused by Cdk5/p35-mediated phosphorylation.

In particular, our data indicate that Cdk5/p35 phosphorylates Ca<sub>v</sub>3.2 in residues S561 and S1987, resulting in increased membrane expression of the channels. These data are consistent with previous studies on the regulation of Ca<sub>v</sub>3.2 channels by phosphorylation using mass spectrometry. Blesneac et al. (2015) reported that these serine residues may be phosphorylated in the mouse brain and recombinant human Ca<sub>v</sub>3.2 channels expressed in HEK293 cells. Likewise, we previously reported that Cdk5 phosphorylates the Ca<sub>v</sub>3.1 isoform in a serine residue at position 2234 (Calderón-Rivera et al., 2015). In contrast, the possibility of a direct effect of Cdk5 on Ca<sub>v</sub>3.2 channels is unlikely given that Cdk5 seems not to affect the activity of target proteins by any mechanism independent of its kinase activity. In this context, it is also worth recalling that Cdk5 may interact with other proteins such as Cyclin E and GSTP1 that act as regulators of its activity by competing for the binding site of its activator p35 (Shupp et al., 2017). However, the functional experiments in the present report were mostly performed in cells overexpressing the Cdk5/p35 complex, which minimizes the possible effects of the regulatory proteins on Cdk5 activity.

In the functional context, a previous report by Blesneac et al. (2015) showed that the phosphorylation of a locus (S442/S445/T446) within the “gating brake,” a functional domain in the intracellular loop connecting repeats I and II of Ca<sub>v</sub>3.2 (Vitko et al., 2007; Arias-Olguín et al., 2008), is of particular importance for the gating of the channels. These studies also showed the presence of 34 phosphorylatable sites for the native channel in the rat brain and 43 for the recombinant human Ca<sub>v</sub>3.2 channel. However, except for residues S442, S445, and T446, the rest of the phosphosites had no effect on the biophysical properties of the channels, suggesting that the functional role of some of them in Ca<sub>v</sub>3.2

**Figure 8.** SNL increases the relative expression of p35 and p25 in the DRG. **A**, Top, Comparative Western blot analysis of p35 and p25 expression in sham-operated animals and rats with allodynia induced by the ligation of the spinal nerves L5–L6. The Cdk5 activators were detected in cell lysates from DRG of L5–L6 14 d after SNL using specific antibodies. Bottom, Corresponding protein band signal intensities of proteins normalized to β-actin levels ( $n = 3$  and 4 independent experiments for p35 and p25, respectively). SNL increases the relative expression of p25 in the DRG at the expense of an apparent decrease in p35. The asterisk denotes a significant difference from the control condition (Table 1). **B**, **C**, Top panels, Comparative Western blot analysis of p35 and p25 protein expression in sham-operated animals and rats with mechanical allodynia induced by the ligation of the spinal nerves L5–L6, in lysates from the spinal nerve SN, the DRG, and the DR. Proteins were detected in lysates from L5–L6 14 d after SNL using specific antibodies to p35 and p25 as indicated. Bottom panels, Corresponding protein band signal intensities of p35 and p25 normalized to β-actin levels to obtain the relative expression of the kinase activators. The bar charts summarize the results of three independent experiments, and the asterisks denote significant differences. Two-way ANOVA was performed for multiple comparisons followed by Bonferroni's tests for pairwise comparisons (Table 1).

**Figure 9.** Contribution of T-type Ca<sub>v</sub> channels to the C component of the cAP. **A**, Mechanical allodynia induced by SNL. Stimulation with von Frey filaments to the plantar surface of the left lower limb (ipsilateral) of control (naive) animals produced a 50% paw withdrawal threshold (PWT) of ~14 g that was maintained throughout the time of evaluation (14 d). The 50% PWT in the ipsilateral side of sham-operated animals did not change significantly. In contrast, SNL significantly decreased (to <4 g) the 50% PWT in the ipsilateral lower limbs in response to stimulation with the von Frey filaments. This altered threshold remained virtually constant from 1 to 14 d, while in the contralateral side there was a significant decrease in the 50% PWT only at 14 d (contralateralization). One-way ANOVA was performed followed by Bonferroni's tests for comparisons (Table 1;  $n = 6$  independent experiments). **B**, Schematic diagram of the experimental setup. Extracellular recordings of cAPs were performed using 300 ms duration stimulation pulses (1.5, 3, 10, and 50 × T) applied at a frequency of 0.2 Hz. **C**, **D**, Representative traces of cAPs recorded in C-type fibers from sham-operated animals and rats with mechanical allodynia induced by ligation of the spinal nerves, as indicated. In both graphs, the black traces illustrate the control condition, the red trace is the voltage trace after the application of the T-type channel antagonist mibefradil (Mib; 500 nM), and the blue trace is after application of the N-type channels blocker ωCtx-GVIA (250 nM). The toxin was added after mibefradil, therefore at the end the action of the two compound was evaluated together. The size of the C component in rats with mechanical allodynia is bigger than the trace in the sham-operated animals. In addition, a decrease in the C component is observed after application of the Ca<sub>v</sub> channel inhibitors. **E**, **F**, The effect of mibefradil and ωCtx-GVIA on the cAPs recorded from sham animals and animals with mechanical allodynia (**E**,  $n = 180$ ; **F**, 210 traces). The bar charts show the comparison of the normalized area under the C component of cAPs (AUC) in the control condition and after the application of mibefradil alone or in combination with ωCtx-GVIA. The asterisk denotes a significant difference from the control condition (Table 1).

could be related to other forms of regulation. Indeed, our data suggest that the phosphorylation of residues S561 and S1987, which may occur in response to an exacerbated expression of Cdk5/p35 after SNL, favors the membrane localization and causes a clustered distribution of the channels in the soma of nociceptive neurons. Interestingly, S561 is located in the central portion of the intracellular loop that connects repeats I and II,

which play important functional roles in Ca<sub>v</sub>3.2, including trafficking of the channels to the plasma membrane (Vitko et al., 2007; Baumgart et al., 2008).

Phosphorylation is an important mechanism of regulation not only of activity but also the membrane location of Ca<sub>v</sub> channels. It has been shown that mimicking the phosphorylation sites at the C-terminal domain of the neuronal Ca<sub>v</sub>1.2 channels affects

the mobility and reveals a dynamic organization of the channels in different signaling complexes (Folci et al., 2018; Heine et al., 2019). This suggests that a tighter or looser association of the channels to different signaling complexes may affect the intracellular signaling process. In addition, the rearrangement of L-type channels in microdomains has been shown to be an important event in pathways that may contribute to cardiac ventricular arrhythmogenesis.

T-type channels are expressed throughout the peripheral nervous system and CNS. Their low activation threshold makes them suitable for functioning around the resting membrane potential (Stuart et al., 1997; Leresche and Lambert, 2017). These channels provide a “window current” that allows the passive entry of Ca<sup>2+</sup>, which contributes to maintain the membrane potential at rest, and influences neuronal excitability. Although a substantial fraction of these channels is inactivated at rest, their recovery from inactivation during brief periods of hyperpolarization generates rebound APs that contribute to the pacemaker capacity of some neuronal types (Chemin et al., 2002; Cain and Snutch, 2010; Canto-Bustos et al., 2014; Lambert et al., 2014). In addition, it has been shown that these channels have the ability to associate and regulate the activity of some K<sub>V</sub> channels contributing to shape the AP firing (Anderson et al., 2010).

Interestingly, our results indicate that Cdk5/p35-mediated Ca<sub>v</sub>3.2 phosphorylation, in addition to favoring channel membrane location, could contribute to guiding the channels to defined subcellular compartments. After SNL, there is a redistribution of Ca<sub>v</sub>3.2 channels in the afferent fibers, as follows: in animals with mechanical allodynia after SNL, the channel proteins were grouped in the soma of the sensory neurons; while in the peripheral region of the nerves their density was significantly lower. These findings suggest that the traffic of the channels to the periphery may be altered or that their mobility from the periphery to the soma might be increased as a consequence of phosphorylation. Here, it is worth recalling that T-type channels contribute to the dendritic depolarization associated with action potential propagation (Stuart et al., 1997; Leresche and Lambert, 2017). Hence, the differential distribution of Ca<sub>v</sub>3.2 channels in response to phosphorylation mediated by the Cdk5/p35 complex could help to explain the increased excitability (manifested as a larger C component of the cAP) of afferent fibers in animals with mechanical allodynia.

On the other hand, previous studies have shown that HVA channel activity may also be regulated by the Cdk5/p35 complex. It has been reported that the L-, P/Q-, and N-type channels are regulated by Cdk5 and that this regulation has relevant presynaptic implications (Su et al., 2012; Furusawa et al., 2014). This regulation seems to be mediated by an interaction between the

**Figure 10.** Intrathecal injection of olomoucine (Olo) reduces mechanical allodynia. **A**, Percentage of the paw withdrawal threshold  $\pm$  SEM in sham-operated (filled circles) and in spinal nerve-ligated animals (open circles) after intrathecal injection of 100  $\mu$ M olomoucine or vehicle (DMSO). A significant increase in the withdrawal threshold was observed after olomoucine injection in animals subjected to SNL. **B**, Comparison of the area under the curve as in **A** in the sham-operated animals, and in spinal nerve-ligated animals after DMSO or Olo intrathecal injection. The Cdk5 blocker partially reverses the effect of the SNL on the paw withdrawal threshold. One-way ANOVA was performed followed by Bonferroni's tests for multiple comparisons (Table 1;  $n = 6$ –11 independent experiments). **C**, The inhibition of Cdk5 activity with olomoucine decreases the C component of the cAP. The cAPs were extracellularly recorded from a preparation that included the SN–DRG–DRL5 in sham and SNL animals, obtained at a  $50 \times T$  stimulation. The bar charts compare the normalized area under the C component. Kruskal–Wallis analysis was performed for multiple comparison followed by Dunn's *post hoc* tests for pairwise comparisons (Table 1;  $n = 120$  traces in each experimental condition). **D**, Blockade of Cdk5 activity with intrathecal injection of olomoucine decreases the area of the C component in both sham and SNL animals. Olomoucine (Olo) treatment occludes the effect of mibefradil (Mib) on the C component of the cAP. Representative traces of cAPs recorded in the absence (control, pink trace) or in the presence of 500 nM mibefradil (green trace) alone, or in combination with 100  $\mu$ M olomoucine (purple trace) from SNL animals. **E**, Blockade of Ca<sub>v</sub>3.2 channel activity with Mib decreases the amplitude of the C component recorded in L5. However, the combined use of Mib and Olo did not have an additive effect on the cAPs area, suggesting that they share the same mechanism of action. Kruskal–Wallis analysis was performed for multiple comparison followed by Dunn's *post hoc* tests for pairwise comparisons (\*\* $p < 0.001$ , Table 1;  $n = 120$  traces in each experimental condition).

channel and RIM1, a protein that influences vesicle docking at the active zone (Gandini and Felix, 2012; Su et al., 2012). It should also be noted that there is experimental evidence suggesting that the Ca<sub>v</sub> $\alpha_2\delta$ -1 auxiliary subunit of HVA Ca<sub>v</sub> channels may play a role in the pathophysiology of neuropathic pain (Field et al., 2006; Li et al., 2006; Gong et al., 2018; González-Ramírez et al., 2018).

In addition to the role Cdk5-mediated phosphorylation on Ca<sub>v</sub>3.2, it may affect TRPV1 (transient receptor potential cation channel subfamily V member 1) and other channels related to chronic pain, including K<sub>V</sub> and other Ca<sub>v</sub> channels (Buraei et al., 2007). It should be mentioned that though Cdk5 can indeed phosphorylate TRPV1 (Pareek et al., 2006, 2007; Xing et al., 2012), evidence that these channels may play a role in determining the C component of a cAP in which primary afferent fibers are lacking. Likewise, it has been reported that Kv2.1 and Kv7.2 neuronal channels are molecular targets of Cdk5 (Cerda and Trimmer, 2011; Erdem et al., 2017). However, the role that these channel play in neuropathic pain remains uncertain. Last, recent evidence suggests that Cdk5 may also play a role in chronic pain by acting on CRMP2 (collapsing response mediator protein 2; Brittain et al., 2012). Interestingly, this functional interaction re-

sults in reduced presynaptic distribution of Ca<sub>v</sub>2.2 and Na<sub>v</sub>1.7 (Yu et al., 2019). Although this regulation of ion channels by Cdk5 would have an opposite effect to that observed by the direct phosphorylation of Cav3.2 channels, studying how these mechanisms are related is an interesting topic for future studies.

The increase in the intracellular concentration of Ca<sup>2+</sup> may promote the enhanced activity of calpain with the consequent cleavage of p35 into p25, which forms a more stable complex with Cdk5 by increasing its activity. When we evaluated the effect of intrathecal olomoucine on the cAPs in the preparations of SN–DRG–DR, the Cdk5 inhibitor was able to occlude the inhibitory effect of the T-channel antagonist mibefradil, suggesting that both compounds share a common mechanism of action. Moreover, olomoucine partially reversed SNL-induced mechanical allodynia. Together, these data show that the increase in the activity of T-type Ca<sub>v</sub>3.2 channels induced by Cdk5-mediated phosphorylation contributes to the increase of the C component of the cAP recorded in the dorsal roots of animals, with allodynia produced by SNL. These findings may help to explain how the alteration induced by nerve injury may cause neuropathic pain. Therefore, in addition to the Ca<sub>v</sub>3.2 channels, Cdk5 and/or its activators could be attractive targets in the development of more effective interventions to relieve pain induced by nerve injury and other diseases of the nervous system associated with chronic pain.
