As one of the thalamic midline nuclei, the thalamic paraventricular nucleus (PVT) is considered to be an important signal integration site for many descending and ascending pathways that modulate a variety of behaviors, including feeding, emotions, and drug-seeking. A recent study has demonstrated that the PVT is implicated in the acute visceral pain response, but it is unclear whether the PVT plays a critical role in the central processing of chronic pain. Here, we report that the neurons in the posterior portion of the PVT (pPVT) and their downstream pathway are involved in descending nociceptive facilitation regarding the development of neuropathic pain conditions in male rats. Lesions or inhibition of pPVT neurons alleviated mechanical allodynia induced by spared nerve injury (SNI). The excitability of pPVT-central amygdala (CeA) projection neurons was significantly increased in SNI rats. Importantly, selective optogenetic activation of the pPVT-CeA pathway induced obvious mechanical hypersensitivity in naive rats. In addition, we used rabies virus (RV)-based and cell-type-specific retrograde transsynaptic tracing techniques to define a novel neuronal circuit in which glutamatergic neurons in the vlPAG were the target of the pPVT-CeA descending facilitation pathway. Our data suggest that this pPVT^{Glu+}-CeA-vlPAG^{Glu+} circuit mediates central mechanisms of descending pain facilitation underlying persistent pain conditions.

Key words: central amygdala; descending facilitation; pain; thalamic paraventricular nucleus; ventrolateral periaqueductal gray

Significance Statement

Studies have shown that the interactions between the posterior portion of the thalamic paraventricular nucleus (pPVT) and central amygdala (CeA) play a critical role in pain-related emotional regulation. However, most reports have associated this circuit with fear and anxiety behaviors. Here, an integrative approach of behavioral tests, electrophysiology, and immunohistochemistry was used to advance the novel concept that the pPVT-CeA pathway activation facilitates neuropathic pain processing. Using rabies virus (RV)-based and cell-type-specific retrograde transsynaptic tracing techniques, we found that glutamatergic neurons in the vlPAG were the target of the pPVT-CeA pathway. Thus, this study indicates the involvement of a pPVT^{Glu+}-CeA-vlPAG^{Glu+} pathway in a descending facilitatory mechanism underlying neuropathic pain.

Introduction

It has been well recognized that the thalamus is the principal gateway for the transmission of various sensory information from the periphery to the cortex (Kolaj et al., 2014). The thalamic midline nuclei, initially considered “nonspecific,” have recently gained recognition for their involvement in a variety of distinct functions, such as stress, motivation and mood (Hsu et al., 2014; Kirouac, 2015). Interestingly, some midline nuclei have been verified to function as novel “nociceptive discriminators” and form two distinct endogenous systems that control noxious responses: the mediodorsal nucleus of the thalamus (MD) that participates in the descending facilitation underlying the

development of mechanical allodynia and the ventromedial nuclei of the thalamus (VMs) that specifically mediates the descending inhibition of thermal hyperalgesia in rats (You et al., 2013).

Recently, the thalamic paraventricular nucleus (PVT), another thalamic midline nucleus, has also attracted increasing attention for its function. Based on anatomic connectivity and functions, the PVT is divided into anterior (aPVT) and posterior (pPVT) portions along the rostrocaudal axis (Li and Kirouac, 2012; Li et al., 2014; Dong et al., 2017). The pPVT is associated with fear and anxiety via projections to the bed nucleus of the stria terminalis (BNST) and the amygdala (Li and Kirouac, 2008; Li et al., 2010; Kirouac, 2015). Interestingly, chemogenetic inhibition of PVT neurons has been shown to attenuate acute pancreatitis-related visceral pain (Jurik et al., 2015), although its mechanisms including its downstream neural circuitry, are not fully understood.

The central amygdala (CeA) is now defined as the “nociceptive amygdala” and contains a population of neurons involved in processing pain-related information (Han et al., 2005; Nakao et al., 2012). Notably, the pPVT has denser projections to the CeA than to other amygdaloid nuclei (Li and Kirouac, 2008; Vertes and Hoover, 2008; Kuramoto et al., 2009), and the pPVT-CeA pathway has been identified to play a vital role in fear learning and memory (Do-Monte et al., 2015; Penzo et al., 2015). Nevertheless, whether the pPVT-CeA pathway is involved in nociception transmission or modulation remains unclear.

There are many complicated neural circuits in the brain stem involved in descending pain modulation, in which the periaqueductal gray (PAG)-rostral ventromedial medulla (RVM)-spinal dorsal horn (SDH) pathway is recognized as the classical and most essential central endogenous descending pain system (Millan, 2002; Heinricher et al., 2009). Therefore, the PAG is considered to be a key site for the integration of descending pain modulation. One strong downstream target of the CeA is the PAG, especially the ventrolateral subregion of the PAG (vIPAG; Rizvi et al., 1991). According to the aforementioned literature evidence, we hypothesize that the pPVT might function through the CeA and vIPAG to affect the endogenous pain modulating system.

Here, using neuroanatomical tracing methods, chemogenetic and optogenetic approaches, we anatomically and functionally define a novel pathway from the pPVT to the vIPAG via the CeA (that is, the pPVT-CeA-vIPAG pathway) that is involved in descending pain facilitation.

Materials and Methods

Animals

Sprague Dawley male rats and VGLUT2-ires-Cre male mice were used. The Sprague Dawley rats were purchased from the Laboratory Animal Center of the Fourth Military Medical University; the animals weighed 260–320 g (specifically, 80–100 g for electrophysiology). The VGLUT2-ires-Cre mice (20–25 g) were purchased from The Jackson Laboratory. The animals were housed in a 12/12 h light/dark cycle with free access to food and water, and all experiments were performed during the light cycle between 8 A.M. and 6 P.M. All procedures were conducted in accordance with the International Association for the Study of Pain guidelines (Zimmermann, 1983) for the care and use of laboratory animals and were approved by the Ethics Committee of Animal Use for Research and Education of the Fourth Military Medical University (Xi'an, People's Republic of China).

Neuronal tract tracing

Neuronal tract tracing was performed on the rats as previously described (Liang et al., 2016). Briefly, the rats were deeply anesthetized with pentobarbital sodium (50 mg/kg, i.p.) and then mounted on a stereotaxic apparatus (Narishige Scientific Instrument Lab). The tracers used in this

study include the anterograde tracer biotinylated dextran amine (BDA; D1956, 10,000 MW; Invitrogen), retrograde tracers Fluoro-Gold (FG; 80014, Biotium), and tetramethylrhodamine-dextran (TMR; D3308, 3000 MW, Invitrogen) that were stereotactically pressure-injected into the related nuclei through different glass micropipettes (internal tip diameter, 50–80 μ m) attached to a 1- μ l Hamilton microsyringe. The injections were performed on the right side according to the atlas of the brain created by Paxinos and Watson (Paxinos and Watson, 2007), and the coordinates were as follows: 2.3–2.5 mm posterior to the bregma, 4.3 mm lateral to the midline, and 8.3 mm ventral to the skull surface for the CeA; 3.2–3.4 mm posterior, 0.3 mm lateral, and 5.6 mm ventral to the bregma, midline, and skull surface, respectively, for the pPVT; and 7.8–8.0 mm posterior, 0.6 mm lateral, and 5.8 mm ventral to the bregma, midline, and skull surface, respectively, for the vIPAG. After surgery, the rats were allowed to survive for 7 d.

BDA (0.06 μ l, 10%, dissolved in distilled water), FG (0.04 μ l, 4%, dissolved in distilled water), or TMR (0.05 μ l, 10%, dissolved in trisodium citrate solution; pH 3.0; Kaneko et al., 1996) were each stereotactically pressure-injected into the CeA, separately. Then, 0.04 μ l of 10% BDA was pressure-injected into the pPVT and 0.04 μ l of 4% FG was pressure-injected into the ipsilateral vIPAG.

Establishment of a pain model

In the present study, we used spared nerve injury (SNI) to establish a neuropathic pain model, which has been reported previously (Decosterd and Woolf, 2000). Briefly, the rats received general anesthesia with pentobarbital sodium (50 mg/kg, i.p.). After disinfection, the sciatic nerve and its three terminal branches on the left side were clearly exposed by small incisions made on the skin and to the biceps femoris muscle in the left thigh. Two ligations were made on the common peroneal and tibial branches with 5–0 silk sutures. Then, the nerves were cut between the ligations, and 2–4 mm of the distal nerve stump was removed. The muscular fascia and skin were closed. Those in the sham group underwent the same surgery procedures, except they did not undergo ligation or the cutting of the nerves.

Behavioral tests

SNI-induced mechanical allodynia was assessed by measuring the paw withdrawal threshold (PWT) of the ipsilateral hind paw. After the rats were acclimated for 30 min, a series of von Frey filaments (Stoelting) from 0.16 to 26.0 g were applied to the plantar surface of the hind paw with a sufficient force to bend the filaments for 5 s. A sharp withdrawal of the hind paw was recorded as a positive response. The minimal value, that elicited at least six positive responses in 10 stimuli for every filament, was recorded as the PWT. The PWT baseline values of the normal rats selected in our experiment were 10–15 g. Experimental subjects had unique number identifiers and the behavioral experimenters were blinded to the animal grouping.

Chemical lesions

A combination of chemical lesions in the pPVT by caused kainic acid (KA; MKBS7052 V, Sigma-Aldrich) and behavioral tests were used to observe the roles of the pPVT in neuropathic pain development. The rats were randomly divided into five groups: sham, SNI, sham + KA, SNI + saline, and SNI + KA. In the SNI + saline or SNI + KA groups, the rats received brain stereotaxic injections of 0.5 μ l of KA (1 mg/ml) or 0.9% saline into the bilateral pPVT (midline, 3.3 mm posterior to the bregma and 5.6 mm ventral to the skull surface), respectively, before the SNI. Behavioral tests with von Frey filaments were conducted on days 4, 7, 10, 14, 21, and 28 after the SNI. After behavioral tests were completed, the rats were perfused with fixative. Neuronal nuclei (NeuN)-labeled neurons and astrocytes labeled by glial fibrillary acidic protein (GFAP) in the pPVT were used to examine and reconstruct the lesion region. Behavioral data collected from the rats in which only lesion areas were restricted to the bilateral pPVT were used for further analysis.

Virus injections and chemogenetics

We used a chemogenetic approach with designer receptors exclusively activated by designer drugs (DREADDs; Farrell and Roth, 2013) to

inhibit pPVT neurons. An AAV virus with the CaMKII α promoter can specifically infect excitatory neurons. Additionally, hM4Di is an artificial receptor modified from human muscarinic acetylcholine receptor M4 (Armbruster et al., 2007; Whissell et al., 2016) that is potently activated by clozapine-N-oxide (CNO). In neurons, the binding of CNO with hM4Di hyperpolarizes the cell membrane and inhibits the action potential of neurons. Based on reports that pPVT neurons are mainly glutamatergic, we used the virus AAV2/9-CaMKII α -hM4Di-mCherry (PT-0017, 7.36×10^{12} genome copies/ml, BrainVTA) to inhibit excitatory neuronal activity in the pPVT. First, the rats received injections of 0.5 μ l of AAV2/9-CaMKII α -hM4Di-mCherry or AAV2/9-CaMKII α -mCherry (PT-01008, 5.84×10^{12} genome copies/ml, BrainVTA) into the pPVT (midline, 3.3 mm posterior to bregma and 5.6 mm ventral to the skull surface), and then SNI surgery was performed 18 d after AAV virus injection. Ten days later, the rats were given von Frey tests before and 30 min after CNO (C4759, 2 mg/kg, LKT Laboratories) administration intraperitoneally. The PWT was measured 40 min after the CNO injection. Finally, the rats were perfused to examine viral infections in the pPVT.

Fluorescence in situ hybridization (FISH) combined with retrograde tract tracing

FISH was used to observe the expression of vesicular glutamate transporters (VGLUT1 and VGLUT2) that are generally considered markers for glutamatergic neurons. Here, we first observed that the pPVT neurons were positive for VGLUT1 or VGLUT2 mRNA and then mainly examined whether the retrogradely labeled pPVT neurons projecting to the CeA expressed VGLUT2 mRNA.

For RNA probe preparation, the preparation methods of the digoxigenin-labeled RNA probes was the same as those described in Ge's article (Ciocchi et al., 2010). The complementary DNA fragment of VGLUT1 (nucleotides 152–1085; GenBank accession No. NM_182993.2; Watakabe et al., 2006) or VGLUT2 (848–2044; NM_080853.2; Nakamura et al., 2007) was cloned into a vector pBluescript II KS(+) (Stratagene). By using linearized plasmids (kindly presented by Hioki, Department of Brain Morphology, School of Medicine, Kyoto University) as template, we synthesized sense and antisense single-strand RNA probes with a digoxigenin RNA labeling kit (Roche Diagnostics).

For double labeling with FISH and immunofluorescence, the following hybridization procedure was conducted according to Hioki's literature (Hioki et al., 2010). Briefly, the rats injected with TMR into the right CeA were deeply anesthetized with sodium pentobarbital (40 mg/kg) and then perfused with 0.01 M PBS (pH 7.4) and 0.1 M phosphate buffer (PB; pH 7.4) treated with 0.1% (v/v) diethyl pyrocarbonate (DEPC; DH098-2, Genview). Then, the sections were hybridized under aseptic conditions to maintain a ribonuclease (RNase)-free state. The free-floating sections were prehybridized for 1–1.5 h in a prehybridization buffer, which consisted of 5 $\times$ saline sodium citrate (SSC; 1 $\times$ SSC = 0.15 M NaCl and 0.015 M sodium citrate, pH 7.0), 2% (w/v) blocking reagent (Roche Diagnostics), 50% (v/v) formamide, 0.1% (w/v) N-lauroylsarcosine (NLS), and 0.1% (w/v) sodium dodecyl sulfate (SDS). Then, 1 μ g/ml of a digoxigenin-labeled VGLUT1 or VGLUT2 riboprobe was added to the prehybridization buffer and sections were incubated for 20–24 h at 58°C. After two washes in 2 $\times$ SSC, 50% (v/v) formamide and 0.1% (w/v) NLS for 20 min at 58°C, the sections were incubated with 20 μ g/ml RNase A for 30 min at 37°C in 10 mM Tris-HCl (pH 8.0), 1 mM ethylenediaminetetraacetic acid and 0.5 M NaCl, followed by two washes with 0.2 $\times$ SSC containing 0.1% (w/v) NLS for 20 min at 37°C.

After the washing and RNase treatment steps, the hybridized sections were incubated overnight at room temperature (RT; 22–24°C) with a mixture of peroxidase-conjugated antidigoxigenin sheep antibody (1:1000, Roche Diagnostics catalog #11-207-733-910, RRID:AB_514500) and rabbit anti-TMR antibody (1:200, Invitrogen catalog #A6397, RRID:AB_1502299) in 0.1 M Tris-HCl (pH 7.5)-buffered 0.9% (w/v) saline (TS7.5) containing 1% blocking reagent (TSB). To amplify the signals for VGLUT1 or VGLUT2 mRNA, we performed the biotinylated tyramine (BT)-glucose oxidase (GO) amplification method (Kuramoto et al., 2009) with a reaction mixture containing 1.25 μ M BT, 3 μ g/ml GO, 2 mg/ml β -D-glucose, and 1% bovine serum albumin (BSA) in 0.1 M PB

for 30 min. The sections were then incubated with Alexa Fluor 594-conjugated donkey anti-rabbit IgG (1:500, Invitrogen catalog #A21207, RRID:AB_141637) in TSB for 4 h and then with FITC-avidin (1:1000, Vector catalog #A-2001, RRID:AB_2336455) in TSB for 2 h. The specificity of the hybridization reaction was verified by processing some sections treated with labeled sense probes instead of with antisense probes. Labeling was not observed under these conditions.

Electrophysiology

A week after TMR injection into the CeA and SNI model, the rats weighing 80–100 g were anesthetized with pentobarbital sodium (50 mg/kg, i. p.) and then decapitated. Coronal slices (400 μ m) containing the pPVT were cut at 2–4°C on a vibrating microtome (Leica VT 1200s) in sucrose artificial CSF (sucrose-aCSF), which contained the following: 2.5 mM KCl, 1.2 mM NaH₂PO₄, 26 mM NaHCO₃, 220 mM sucrose, 6 mM MgSO₄, 0.5 mM CaCl₂, and 10 mM glucose with a pH of 7.4. Sucrose-aCSF solutions were bubbled with carbogen gas (95% O₂ and 5% CO₂). Then, the brain slices were transferred to a submerged recovery chamber with oxygenated normal-sodium aCSF containing the following: 124 mM NaCl, 2.5 mM KCl, 2 mM MgSO₄, 1 mM NaH₂PO₄, 25 mM NaHCO₃, 2 mM CaCl₂, and 37 mM glucose. The slices were incubated for 2 h at RT before recording.

The slices were transferred to a recording chamber (volume: 0.5 ml) that was mounted on a fixed-stage upright microscope (BX51W1, Olympus). The slices were continuously perfused with normal-aCSF bubbled with carbogen gas at a rate of 2–3 ml/min. The patch pipettes were constructed with a P-97 micropipette puller (Sutter Instruments) from borosilicate glass capillary tubes (outside diameter: 1.5 mm, inside diameter: 0.84 mm with microfilaments, 1B150F-4, World Precision Instruments). The pipette resistances were 3–5 M Ω when filled with the internal pipette solution, which contained the following: 130 mM K-glucuronate, 5 mM NaCl, 15 mM KCl, 0.4 mM EGTA, 10 mM HEPES, 4 mM Mg-ATP, and 0.2 mM Tris-GTP. This solution was titrated to pH 7.3 with KOH. The osmolality of the pipette solutions was adjusted to 290–300 mOsm. Whole-cell patch-clamp recordings were made from TMR-containing neurons projecting to the CeA that were visualized by epifluorescence using a tetramethyl rhodamine isothiocyanate (TRITC) filter set (U-HGLGPS, Olympus) with a monochrome CCD camera (IR-1000E, DAGE-MTI) and monitor. The neurons were recorded using a Multiclamp 700B amplifier (Molecular Devices). The pCLAMP software (v. 10.02, Molecular Devices) was used to acquire and analyze the data. The signals were low-pass filtered at 2.6 kHz, digitized at 10 kHz (Digidata 1322A, Molecular Devices), and saved on a computer for offline analysis. Before collecting the data, the neurons were given at least 3 min to stabilize. Spontaneous EPSCs (sEPSCs) and the minimum current required to elicit an action potential (rheobase current) were used to investigate SNI-induced changes in neuronal excitability in the pPVT. The sEPSCs of neurons retrogradely labeled with TMR were voltage-clamped and recorded at –60 mV after blocking GABAergic transmission by picrotoxin (100 mM, Sigma), a GABA_A receptor antagonist. The rheobase current was measured in current-clamp mode by injecting pulse steps of depolarizing current (steps of 5 pA for 15 ms) until action potentials were induced. The threshold of action potentials was measured at the beginning of the fastest rising phase. In all recordings, the initial access resistance was $\leq$ 30 M Ω and monitored throughout the experiment. Data were discarded if the access resistance changed by >15% during the experiment. Seven (control group) or six (SNI group) rats were used for electrophysiology recordings. One to two coronal brain slices (400 μ m for each) containing the pPVT were cut from one animal, and only one neuron in the pPVT was recorded for the electrophysiology from each slice.

To identify the morphologic properties of the recorded neurons, 0.2% biocytin (Sigma) was added to the recording pipette solution. After recording, the brain slices were immediately fixed in 4% paraformaldehyde made with 0.1 M PB for 4 h at RT. In addition, brain slices were subsequently stored in 30% sucrose solution overnight at 4°C. After a thorough washing with PBS, the tissue was incubated with a rabbit anti-TMR antibody, 1:200 (Invitrogen catalog #A6397, RRID:AB_1502299), for 24 h followed by an incubation in a mixture of FITC-avidin, 1:1000

Virus injections and optogenetics

To optogenetically (Park and Carmel, 2016; Rajasethupathy et al., 2016) activate the pPVT-CeA pathway, a volume of 0.3 μ l AAV2/9-CaMKIIa-ChR2(E123T/T159C)-mCherry (PT-0005, 4.30×10^{12} genome copies/ml, BrainVTA) was injected into the right pPVT. The light-sensitive protein channel rhodopsin (ChR2) can induce the opening of cation channels, promote neuronal depolarization, and then evoke an action potential to activate neurons under the excitation of blue light (the maximum excitation peak is near 470 nm). AAV2/9-CaMKIIa-mCherry (PT-01008, 5.84×10^{12} genome copies/ml, BrainVTA) was used as a control virus. The rats were allowed to survive for five weeks. Then, all rats were anesthetized with isoflurane by an animal anesthesia machine (HSIV-130105055, Shanghai Raymain Information Technology Co, Ltd.), and fiber optic ferrules (0.22 NA, 200- μ m core, 13-mm length, Doric Lenses) were then implanted into the right CeA (the depth was 0.2 mm more superficial than that for the brain stereotaxic injection), for which the power density at the tip was 15–20 mW as detected by the optical power meter (Q8230, ADVANTEST). Five days later, photostimulation was performed on the rats with fiber optic ferrules in the CeA by connecting the ferrule to a fiber optic cable with a rotary joint (Doric lenses), and then attaching to a fiber-coupled 473-nm blue laser (BL473T8-150FC, Shanghai Laser and Optics Co) with an ADR-800A adjustable power supply by another fiber optic cable. The output laser power from the fiber optic cable was measured by using a photometer (Thor Labs) and set to ~ 15 mW/mm², as the power loss through the ferrule-cable connection was 10–20%. The rats were acclimated for 30 min before receiving stimulation in the advanced brain function laboratory. For von Frey tests, a 15-s stimulation (473 nm at 20 Hz, 15-ms pulse, 15 mW/mm²) with a 10-s break following each stimulation was performed for each animal until the mechanical thresholds were detected. Finally, the rats were perfused, and virus injections were further observed.

Brain tissue preparation

After deep anesthesia with pentobarbital sodium (50 mg/kg, i.p.), the rats were perfused with 150 ml of 0.01 M PBS (pH 7.4) followed by 500 ml of 4% (w/v) paraformaldehyde in 0.1 M PB (pH 7.4) for ~ 1.5 h. Subsequently, brains were removed and immersed in 30% (w/v) sucrose solution (4°C) for at least 48 h. The injection sites for tracers were coronally cut into 40 μ m sections and sites containing projections were cut into 35- μ m-thick sections. Sections were cut on a freezing microtome (CM1950, Leica).

Immunohistochemistry study

In the present study, fluorescent tracer injections were observed directly under an epifluorescence microscope (BX-60; Olympus), and a nickel-diaminobenzidine (DAB)-H₂O₂ technique was applied to visualize the sites of the BDA injections into the CeA. If the injection sites were successful, brain slices of the projection sites were selected for further study. All the antisera used here are listed in Table 1.

Nickel-DAB-H₂O₂ techniques were only used for the BDA injection and projection sites in our experiment. The primary and secondary antisera involved were omitted for BDA staining because it was biotinylated. Brain slices were incubated with an avidin-biotinylated peroxidase complex for 2–4 h at RT. Subsequently, the slices were allowed to react for 15–30 min in 20% (w/v) DAB reagent by adding 0.3% (v/v) H₂O₂. The 20% (w/v) DAB reagent for four to five brain sections was prepared by dissolving 1 mg of DAB (48596LMV, Sigma) in 5 ml of 0.05 M Tris-HCl (pH 7.6) with 10% (v/v) nickel ammonium sulfate.

Immunofluorescent histochemical methods were used to evaluate the double-labeling of NeuN/GFAP and FG/FOS in the pPVT and FG/BDA in the CeA and the triple-labeling of FG/BDA/FOS in the CeA. Briefly, the sections were incubated with primary antisera for 18–24 h at 4°C in 0.01 M PBS containing 1% (v/v) normal donkey serum, 0.3% (v/v) Triton X-100, 0.02% (w/v) sodium azide, and 0.12% (w/v) carrageenan (pH 7.4). Then, the sections were incubated with secondary antisera (fluorescein-labeled IgG) for 6–8 h at 4°C. If necessary, the sections were incubated with tertiary antisera for 2–4 h in 0.01 M PBS with 0.3% (v/v) Triton X-100 at 4°C.

In the negative control experiments, the primary antisera were omitted, and the other steps were the same as those for the experimental groups.

Electron microscopy observation

An electron microscopic analysis of pre-embedding immunoperoxidase labeling (Lu et al., 2015) was used to reveal the synaptic connections between BDA-immunopositive terminals and neurons retrogradely labeled with FG in the CeA. One week after the tracer injections, the rats were deeply anesthetized and transcardially perfused with 150 ml of 0.01 M PBS and then 500 ml of 0.1 M PB containing 4% (w/v) paraformaldehyde, 0.1% (v/v) glutaraldehyde, and 15% (w/v) saturated picric acid for ~ 0.5 h. Subsequently, brains were removed immediately, postfixed for 2–4 h, and cut into 50- μ m coronal sections by a vibratome (Microslicer DTM-1000; Dosaka EM). The injection sites were checked under an epifluorescence microscope. Only animals that received successful injections into both the pPVT and vIPAG were used for additional experiments.

The sections were placed into 0.1 M PB containing 25% (w/v) sucrose and 10% (v/v) glycerol for 30 min and freeze-thawed with liquid

nitrogen for 2–3 s. The sections were then blocked in 20% (v/v) normal donkey serum for 40 min at RT. For double immunolabeling of FG/BDA, the sections were incubated with rabbit anti-FG IgG for 24 h at a concentration of 1:200 (Millipore catalog #AB153-I, RRID:AB_2632408) at 4°C, then further incubated overnight at RT with goat anti-rabbit IgG antibody conjugated to 1.4-nm gold particles at a concentration of 1:200 (Nanoprobes catalog #2003, RRID:AB_2687591). The antisera were diluted in 0.05 M Tris-buffered saline (TBS; pH 7.4) containing 2% (v/v) normal donkey serum. Subsequently, the sections were processed for silver enhancement with an HQ Silver kit (Nanoprobes) and then incubated with an ABC reagent (Vector) diluted to a concentration of 1:100 in 50 M TBS for 3–4 h at RT for a DAB reaction.

Next, the sections underwent osmification with 1% OsO₄ in 0.1 M PB for 25 min, counterstaining with 1% uranyl acetate, and dehydration before being embedded flat in Durcupan resin (Fluka) and mounted on

silane-coated glass slides. After polymerization for 48 h at 60°C, small pieces containing the CeA were cut into 70-nm-thick sections on an ultramicrotome (Reichert-Nissei Ultracut S, Leica). The ultrathin sections were then imaged.

Anatomical tracing by recombinant rabies virus (RV)-based and cell-type-specific retrograde transsynaptic tracing techniques

To identify the specific neurons within the vIPAG targeted by the pPVT-CeA pathway, we used a technique combining a Cre-dependent, cell-type-specific anterograde-tracing virus with the recombinant RV-based retrograde transsynaptic tracing (Wickersham et al., 2007; Callaway and Luo, 2015) in VGLUT2-ires-Cre mice. Here, the elongation factor 1- α (Ef1a) promoter, a wide expression promoter, was used. To ensure the viruses were expressed in Cre mice, the double-floxed inverse orientation (DIO) was needed in conjunction with the Cre recombinase. For

anterograde tracing, the AAV2/9-Ef1a-DIO-EYFP virus was injected into the right pPVT. For retrograde transsynaptic tracing, the recombinant RV system was injected into the right side of the vIPAG in sequence. The RV, whose glycoprotein (G) gene is deleted from the genome (RV Δ G), cannot spread across synapses. G complementation enables the transsynaptic spread of RV Δ G to presynaptic neurons. The virus particles formed by the RV were packed with the fusion protein of the envelope protein (EnvA) of the recombinant avian sarcoma virus, which can specifically recognize the EnvA receptor TVA to specifically infect cells. With the aid of helper viruses (AAV-Ef1a-DIO-EGFP-TVA and AAV-Ef1a-DIO-RVG), RV-EnvA- Δ G can be used to perform cell-type-specific retrograde transsynaptic tracing in specific types of neurons. The viruses involved and the specific steps were introduced as follows. On day 1, 0.2 μ l of AAV2/9-Ef1a-DIO-EYFP (PT-0023, 7.29×10^{12} genome copies/ml, BrainVTA) was stereotactically injected into the right pPVT (1.58 mm posterior to the bregma, 0.05 mm lateral to the midline, and 3.05 mm ventral into the skull surface) and the helper virus mixture (1:1) of AAV2/9-Ef1a-DIO-EGFP-TVA (PT-0021, 7.32×10^{12} genome copies/ml, BrainVTA) and AAV2/9-Ef1a-DIO-RVG (PT-0023, 7.29×10^{12} genome copies/ml, BrainVTA) was stereotactically injected into the right vIPAG (4.60 mm posterior to the bregma, 0.05 mm lateral to the midline, and 2.90 mm ventral

to the skull surface) of VGLUT2-ires-Cre mice, which allowed EGFP-TVA and RVG to be selectively expressed in VGLUT2-containing neurons. On day 21, 0.2 μ l of RV-EnvA- Δ G-dsRed [R01002, 2.20×10^8 infectious units (IFU)/ml, BrainVTA] was injected into the vIPAG at the same injection site in a biosafety-level-2 environment. The mice were allowed to survive for 7 d and then were transcardially perfused with 4% paraformaldehyde in PB; their brains were extracted for observation by confocal laser scanning microscopy.

Image acquisition

The immunohistochemical images were captured under a light microscope (AH-3, Olympus) and saved as TIFF files. The ultrathin sections for pre-embedding immunoperoxidase labeling were examined with a JEM-1230 electron microscope (JEOL) and the digital micrographs were captured with a Gatan 832 CCD camera (Gatan). The digital images were manipulated and modified (5–10% contrast enhancement) in Photoshop CS2 and then saved as TIFF files. Single-labeled immunofluorescent images were obtained with an epifluorescence microscope (BX-60, Olympus). The double-labeled and triple-labeled immunofluorescent slices involved in the immunofluorescence histochemical staining, electrophysiology, *in situ* hybridization, and anatomic tracing by the recombinant RV-based and cell-

type-specific retrograde transsynaptic tracing techniques were taken using a confocal laser scanning microscope (CLSM; FV1000, Olympus). Digital images were captured by FLUOVIEW software (FV10-ASW 1.7, Olympus), and saved in an OIB format (image format in FLUOVIEW software), and ultimately converted into TIFF files.

Statistical analysis

Two-way repeated measures ANOVA with a *post hoc* analysis of the Bonferroni method was used to determine statistical significance in behavioral experiment outcomes including chemical lesions, chemogenetic manipulation results and optogenetic findings. The quantitative analysis of the NeuN-labeled neurons, TMR-labeled and TMR/VGLUT2 mRNA double-labeled neurons and FG-positive and FG/FOS-positive neurons in the pPVT were estimated by stereological methods (Coggeshall, 1992). The analysis was performed as described previously (Polgár et al., 2004) by using a modification of the optical disector method with the aid of Stereo Investigator software (MicroBright-Field). A χ^2 test was used to test the significant difference in the percentage of FG retrogradely labeled neurons that expressed FOS between sham and SNI animals. The electrophysiological data were expressed as means $\pm$ SDs and *n* refers to the number of recorded neurons. The cumulative probabilities of the inter-event intervals and the amplitudes of the sEPSCs were compared using the Kolmogorov–Smirnov test. An independent two-sample *t* test was used to analyze the differences between two groups (for example, the difference in the rheobase current between the SNI and the sham groups); $p < 0.05$ was considered significant. All statistical analyses were performed with GraphPad Prism 7.04 software.

Results

Lesioning or the inhibition of pPVT neurons attenuated SNI-induced mechanical allodynia

To examine the role of pPVT neurons in central nociceptive processing and modulation, we injected KA into the pPVT to lesion local neurons in the rats. One sample of the rostro-caudal extent of the lesion sites and its representative pictures from the same rat are shown in Figure 1A,B. The NeuN-labeled neurons (red) were counted to display the lesion effect (Fig. 1B–G). The

corresponding quantitative analysis demonstrated that the number of NeuN-labeled neurons in the SNI + KA group was significantly less than that in the SNI + saline group ($t_{(10)} = 17.03$, $p < 0.001$, *t* test; Fig. 1H). Astrocyte proliferation was also observed after KA lesions (Fig. 1F1,F2). In the current study, the rats with SNI surgery showed long-lasting mechanical allodynia starting on postoperative day (POD) four and peaking on POD10 ($F_{(6,35)} = 5.123$, $p = 0.0007$, two-way ANOVA with Bonferroni correction; Fig. 1I). Lesioning pPVT neurons resulted in a small but significant reduction in SNI-induced behavioral hypersensitivity from POD 7 to POD 10 ($F_{(6,35)} = 2.576$, $p = 0.0358$, two-way ANOVA with Bonferroni correction; Fig. 1I) although the PWTs in the SNI+KA group were still significantly lower than those of sham rats ($F_{(6,35)} = 3.673$, $p = 0.0062$, two-way ANOVA with Bonferroni correction; Fig. 1I).

Next, we used DREADDs to test whether selective inhibition of pPVT neurons in the rats inhibited SNI-induced behavioral responses (Fig. 2A). The AAV-hM4Di injection sites in the pPVT were shown in Figure 2B,C. Notably, the administration of CNO on day 10 after the SNI completely blocked mechanical allodynia (hM4Di-CNO vs hM4Di-saline by post-saline/CNO: $F_{(1,10)} = 58.54$, $p < 0.001$; post-saline/CNO vs pre-saline/CNO in the hM4Di-CNO group: $F_{(1,10)} = 43.11$, $p < 0.001$; hM4Di-CNO vs mCherry-CNO by post-CNO: $F_{(1,10)} = 42.27$, $p < 0.001$; SNI-post CNO vs baseline-post-CNO in the hM4Di-CNO: $F_{(1,10)} = 2.704$, $p = 0.0662$, two-way ANOVA with Bonferroni correction; Fig. 2D), further supporting that active pPVT neurons mediate the development of neuropathic pain.

The pPVT–CeA projection neurons in the pPVT express VGLUT2 mRNA

Previous reports show that the CeA has emerged as an important brain center for pain modulation and has dense fibrous connections with the PVT. To explore the downstream circuit-mediated pPVT-

involved descending nociceptive facilitation pathway, after FG was microinjected into the right CeA of the rats (Fig. 3*A,B1,B2*), neurons retrogradely labeled with FG were observed in the ipsilateral PVT, especially in the pPVT (Fig. 3*C1,C2*), providing morphologic evidence of the pPVT-CeA neuronal circuit in the rats.

Additionally, we used FISH to identify whether CeA-projecting pPVT neurons were glutamatergic. As shown in Figure 4*A1–A4*, we found that many neurons in the pPVT were positive for VGLUT2 mRNA but not for VGLUT1 mRNA. Subsequently, visualizing the TMR injected into the CeA (Fig. 4*B1–B3*), we

determined that $\sim 98\%$ of the TMR-labeled CeA-projecting neurons (red) in the pPVT expressed VGLUT2 mRNA (green; Fig. 4C–F). No VGLUT2 mRNA-expressing cells were observed when the sections were treated with labeled sense probes (Fig. 4G–I).

SNI increased the excitability of pPVT-CeA projection neurons

We used FOS staining to examine neuronal responses to the nerve injury in the pPVT in the rats (Fig. 5A–F) and found that

nearly 92.1% of the FG-labeled CeA-projecting pPVT neurons (red) expressed FOS protein (green) in the SNI group and 28.6% expressed FOS protein in the sham group (Fig. 5G). There was a significant difference between sham and SNI groups in the percentage of FG retrogradely labeled neurons that express FOS ($\chi^2 = 31.104$, $p < 0.001$, χ^2 test; Fig. 5G), indicating the more activation of the pPVT-CeA neuronal pathway after SNI model.

Thus, we performed whole-cell patch-clamp recordings on pPVT-CeA projection neurons in the rats. Biocytin was injected

Figure 6. The injection site of TMR in the CeA and recorded pPVT-CeA projecting neuron for electrophysiology. **A1, A2**, The injection site of TMR in the CeA and Nissl's staining of the adjacent slice. Scale bar = 50 μ m (**A2**; applied in **A1**). **B1, B2**, TMR retrogradely labeled neurons (red) in the pPVT at low and high magnifications. **C1, C2**, The recorded neuron, filled with biocytin and visualized with FITC-conjugate avidin (green). **D1, D2**, Merged images showing that the biocytin-filled neuron is the TMR retrogradely labeled neuron. into the recorded projecting neurons labeled with TMR (red) in the pPVT to confirm that the recorded neurons (green) were pPVT-CeA projection neurons (Fig. 6).

Compared with the sham group, both the amplitude and frequency of sEPSCs were increased in the SNI group (Fig. 7A–C). The sEPSC amplitude increased from -14.61 ± 2.84 pA in the sham group ($n = 10$) to -19.33 ± 6.36 pA in the SNI group ($n = 9$; $p < 0.01$, Kolmogorov–Smirnov test; Fig. 7C, left). The sEPSC frequency was also significantly increased from 3.75 ± 2.08 Hz in the sham group ($n = 10$) to 5.7 ± 3.66 Hz in the SNI group ($n = 9$; $p < 0.01$, Kolmogorov–Smirnov test; Fig. 7C, right).

To further investigate specific neuronal excitability, we recorded TMR labeled CeA-projecting pPVT neurons. aCSF with 10 μ M CNQX, 100 μ M AP-5, and 100 μ M picrotoxin was used to eliminate the influence of excitatory and inhibitory transmission. The rheobase current (the minimum current required to elicit an action potential) was measured by using current-clamp mode, and sample traces for the sham and SNI groups were shown in Figure 7D. Compared with the sham group ($n = 11$), the rheobase current in the SNI group ($n = 10$) was significantly decreased from a mean of 23.6 ± 5.9 to 16 ± 3.9 pA ($t_{(17)} = 3.426$, $p = 0.003$, t test; Fig. 7E, left panel). Meanwhile, the

Figure 7. The excitability of pPVT-CeA projecting neurons is increased in neuropathic pain rats. **A**, Sample traces of sEPSCs of recorded pPVT-CeA projecting neurons in the sham and SNI groups. **B**, Cumulative distributions of the amplitudes (left) and inter-event intervals (right) of the sEPSC of the sham group ($n = 10$, black line) and the SNI group ($n = 9$, red line). The mean cumulative distribution of the sEPSC amplitude in the SNI group is significantly shifted to higher amplitudes (** $p < 0.01$), and the mean cumulative distribution of the sEPSC interevent intervals in the SNI group is significantly shifted to shorter durations (** $p < 0.01$). **C**, Graph showing that the sEPSC amplitude and frequency are significantly increased in the SNI group (** $p < 0.01$). **D**, Sample traces of minimal depolarizing current induced action potential in the sham group and the SNI group. **E**, Graph showing that SNI decreases the rheobase current (** $p < 0.01$), and increases the mean RMP (* $p < 0.05$), with no significant change in the firing threshold and spike amplitude.

mean resting membrane potential (RMP) was increased from -66.5 ± 8 mV in the sham group to -59.4 ± 4.3 mV in the SNI group ($t_{(17)} = -2.467$, $p = 0.023$, t test; Fig. 7E). However, there were no significant changes in the firing threshold (-33 ± 4.8 mV in the SNI group vs -32.2 ± 5.4 mV in the sham group, $t_{(17)} = 0.225$, $p = 0.825$, t test; Fig. 7E) or spike amplitude (-69 ± 9.2 mV in the SNI group vs -69.9 ± 8.8 mV in the sham group, $t_{(17)} = 0.913$, $p = 0.373$, t test; Fig. 7E). These results

indicated that the excitability of the pPVT-CeA projecting neurons was increased in neuropathic pain conditions.

Optogenetic activation of the pPVT-CeA pathway induced mechanical allodynia

We employed an optogenetic approach to activate the pPVT-CeA pathway in the rats and observed its effects on the mechanical nociceptive threshold (Fig. 8A). The mCherry-expressing axonal terminals were observed in the CeA (Fig. 8C3) after an intra-pPVT injection of AAV virus (Fig. 8B,C1,C2); the optic fiber was placed just above the CeA (Fig. 8C3,C4). Activation of the pPVT-CeA pathway by blue light significantly decreased the PWTs in naive rats (light on vs light off in ChR2-mCherry group: $F_{(1,10)} = 6.996$, $p = 0.0245$, two-way ANOVA with Bonferroni correction; Fig. 8D). The animals that received the virus without ChR2 expression did not show any differences while the light was on (ChR2-mCherry vs mCherry in the light on state: $F_{(1,10)} = 5.883$, $p = 0.0357$, two-way ANOVA with Bonferroni correction; Fig. 8D). Therefore, in naive rats, specific activation of the pPVT-CeA pathway is sufficient to evoke mechanical allodynia.

Morphologic evidence for the involvement of the pPVT-CeA-vIPAG pathway in pain modulation

To further study the downstream target of the pPVT-CeA pathway, we investigated the vIPAG based on its role as a key site for the integration of nociceptive signals and the connections with the CeA to outline the pPVT-CeA-vIPAG pathway by immunofluorescence and electron microscopy. After BDA was injected into the CeA of the rats (Fig. 9A,B1,B2), projecting BDA axonal fibers were observed in the PAG, particularly in the vIPAG (Fig. 9C1,C2).

Combining the anterograde tracer BDA that was injected into the pPVT with the retrograde tracer FG that was injected into the vIPAG of the rats, the representative injection sites were shown in Figure 10A2,B2. The rostro-caudal extent of the related images were displayed in Figure 10A1,B1. The neurons retrogradely labeled with FG (green; Fig. 10C) mainly occupied

the medial part (CeM) of the CeA and were also observed in the lateral (CeL) and capsular parts (CeC) of the CeA. The BDA-labeled fibers and terminals (red) were found sparsely in the CeA, especially in the CeL and CeC, respectively (Fig. 10C). The high-power images showed that BDA-labeled fibers and terminals (red) contacted FG-labeled neurons (green) in the CeA (Fig. 10D–F).

Figure 8. Optogenetic activation of the pPVT-CeA pathway induces mechanical allodynia. **A**, The constructs as well as the sequences of the adeno-associated viruses (AAV2/9-CaMKIIa-ChR2-mCherry and AAV2/9-CaMKIIa-mCherry) and the experimental procedures. **B**, The rostro-caudal extent of the virus injection sites in the right pPVT (the area in the white frame in **C1** is magnified in **C2**) and virus labeled axonal fibers and terminals in the CeA (**C3**). The optic fiber trace and its tip site are shown in **C3** (white dotted outline) and **C4** (black dotted outline). **B**, **C** are coming from the same rat. LA: lateral nucleus of amygdala; BLA: basolateral nucleus of amygdala. Scale bars = 200 μ m (**C4**; applied in **C1**) and 100 μ m (**C3**; applied in **C2**). **D**, Light activation of the PVT-CeA pathway results in a significant decrease in the PWTs in naive rats ($n = 6$ in each group); * $p < 0.05$, light on versus light off in ChR2-mCherry group; + $p < 0.05$, ChR2-mCherry versus mCherry in state of light on.

Furthermore, electron microscopy confirmed the synaptic connections between the BDA-labeled axon terminals and FG-labeled neurons in the CeA (Fig. 10G,H). Specifically, BDA-labeled axonal terminals made asymmetric synapses with FG-labeled dendrites in the CeA, suggesting that the axon terminals from the pPVT might make excitatory synapses with the CeA neurons projecting to the vIPAG.

To investigate the role of the pPVT-CeA-vIPAG pathway in the pain transmission process, we conducted FOS immunostaining to observe neuronal activity in the CeA of the rats with SNI. We found FOS expression (red) in some CeA neurons that received pPVT input (BDA-labeled axonal terminals, green) and projected to the vIPAG (FG-labeled neurons, blue; Fig. 11).

Glutamatergic neurons in the vIPAG are downstream targets of the pPVT-CeA pathway

Considering that the majority of the fibers projecting from the pPVT to the CeA were glutamatergic and most of the CeA projection neurons were GABAergic inhibitory neurons (Lu et al.,

2015; Tovote et al., 2016), we hypothesized that the neurons downstream of the pPVT-CeA pathway in the vIPAG produced analgesia so that the pPVT-CeA-vIPAG pathway could play a facilitating role in pain transmission. It has been shown in a previous study that glutamatergic neurons are important analgesic neurons in the vIPAG (Tovote et al., 2016). Next, the VGLUT2-ires-Cre mice were used to evaluate whether these vIPAG neurons receiving CeA input were excitatory. The specific procedures and viruses are shown in Figure 12A,B. The Cre-dependent AAV2/9-EYFP anterograde virus was injected into the pPVT (Fig. 12C1), and the anterogradely labeled axonal terminals (green) from the pPVT were obviously distributed in the CeA and BLA (Fig. 12D1–D3). In addition, after an injection of Cre-dependent AAV2/9-TVA RVG and Rabies-EnvA- Δ G into the vIPAG of the VGLUT2-ires-Cre mice (Fig. 12C2), we found that retrograde transsynaptic labeled neurons (red) were observed in the CeA, especially in the CeM, which indicated that projection fibers from CeA neurons contacted glutamatergic neurons in the vIPAG (Fig. 12E1–E3). Importantly, we further observed

Figure 9. The results of anterograde nerve tract tracing by BDA from CeA to vPAG in the rats. **A**, The rostro-caudal extent of BDA injection sites in the CeA (red) in consecutive coronal brain section. **B1, B2**, The BDA injection site in the CeA and Nissl's staining of the adjacent section. **C1, C2**, The BDA labeled axonal terminals (black arrows) in the vPAG. The black square area in **C1** is enlarged and displayed in **C2**. **A–C** are coming from the same rat. dm: dorsomedial subregion of the PAG; dl: dorsolateral subregion of the PAG; l: lateral subregion of the PAG; vl: ventro-lateral subregion of the PAG; DR: dorsal raphe nucleus. Scale bars = 200 μ m (**C1**); applied in **B1, B2** and 50 μ m (**C2**).

that the virus-labeled glutamatergic axonal terminals from the pPVT closely contacted the Rabies-labeled CeA neurons (Fig. 12F1–F3).

Discussion

The present study defined a pPVT-CeA-vPAG neural pathway through which descending nociceptive facilitation was generated. It was demonstrated that the inactivation of pPVT neurons attenuated SNI-induced neuropathic pain. In contrast, pPVT-CeA projecting neurons were activated, and their excitability increased in SNI rats. Optogenetic activation of the pPVT projection fibers in the CeA produced mechanical hypersensitivity in naive rats. In addition, we established a pPVT^{Glu+}-CeA-vPAG^{Glu+} descending nociceptive pathway, which showed that CeA neurons received glutamatergic pPVT projections and sent projections to the glutamatergic neurons in the vPAG to contribute to neuropathic pain signaling.

The PVT is now notable not only for its extensive brain connectivity (Chen and Su, 1990; Bhatnagar and Deutch, 1998) but also for its involvement in stress (Bhatnagar et al., 2002), anxiety-like responses (Li et al., 2010), fear (Li et al., 2014; Penzo et al., 2015), etc. Recently, the function of the PVT in nociception transmission and modulation was disclosed in visceral pain (Jurik et al., 2015) and chronic musculoskeletal pain (Chen et al., 2010). However, the underlying neuronal circuit and specific mechanism are rarely reported. The PVT receives projections from some nuclei located in the brainstem, such as the lateral subnucleus of the parabrachial nucleus (PBN; Krout and Loewy, 2000b; Liang et al., 2016) and PAG (Krout and Loewy, 2000a). The PBN is considered an important relay point for nociceptive

information being sent to the forebrain (Fulwiler and Saper, 1984). The brain stem inputs to the PVT suggest that it has a role in pain transmission and regulation. In the present study, we found that lesion or inhibition of the pPVT neurons can effectively alleviate mechanical allodynia in SNI rats, which indicates that the pPVT participates in the transmission or regulation of pain signals and causes an increase in pain behaviors. It was shown that inhibiting the activities of pPVT neurons by DREADDs reversed the PWTs of SNI rats to baseline but lesioning pPVT neurons with KA did not completely relieve the mechanical allodynia induced by SNI. To exclude the effect of CNO metabolites on the central nervous system, a control virus was included in the experiment. However, CNO administration in the SNI-mCherry group did not affect the mechanical allodynia. It is known that KA can nonspecifically damage all neurons in the injected area. However, the virus with the CaMKIIa promotor can specifically silence excitatory neurons. The different effects of the two methods may be attributed to the different phenotypes of influenced neurons. Moreover, we observed glial proliferation in the pPVT after KA lesion, which may also be responsible for the different effects on sensory thresholds. The MDs participate in the descending facilitation of mechanical hyperalgesia and the VMs are specifically involved in the descending inhibition of heat hyperalgesia. Therefore, the MD and VM nuclei have been verified to function as novel nociceptive discriminators to form two distinct endogenous systems in the control of mechanically evoked and heat-evoked noxious responses (You et al., 2013). Although we did not analyze the function of the pPVT in thermal allodynia, our results show that inhibiting pPVT neurons could reduce mechanical allodynia and that the pPVT could function to activate the endogenous descending facilitation system.

Figure 10. Neuronal connectivity on the pPVT-CeA-vIPAG pathway. **A1**, The rostro-caudal extent of BDA injection sites in the pPVT (black) in consecutive coronal brain section. **B1**, The rostro-caudal extent of FG injection sites in the vIPAG (black) in consecutive coronal brain section. **A2**, Representative photomicrograph showing the injection site of BDA into the right pPVT (black). 3v: the third ventricle. **B2**, Representative photomicrograph showing the injection site of FG into the right vIPAG (bright color). Aq: aqueduct. Scale bar = 200 μ m (**A2**, **B2**). **C1**, **C2**, The distribution of BDA-labeled axon terminals (red) and FG-labeled neurons (green) in the CeA. CeC: capsular part of the CeA; Cel: lateral part of the CeA; CeM: the medial part of the CeA. Scale bars = 100 μ m (**C1**) and 50 μ m (**C2**). **D1**, **D2**, The FG-labeled neurons in the CeA after tracer was injected into the vIPAG. **E1**, **E2**, The BDA-labeled fibers and axonal terminals in the CeA projected from the pPVT. **F1**, **F2**, The connections between BDA-labeled axonal terminals and FG-labeled neurons (white arrows in **F2**). The white square area in **F1** is enlarged and displayed in **D2–F2**. Scale bars = 20 μ m (**F1**; applied in **D1**, **E1**) and 10 μ m (**F2**; applied in **D2**, **E2**). **A–F** are coming from the same rat. **G**, **H**, The asymmetric synapses (black arrowheads) are formed by BDA anterogradely labeled axonal terminals (Ax-BDA) and FG-labeled postsynaptic dendrites (Den-FG). Scale bar = 250 nm (**G**, **H**).

Figure 11. Activation of the pPVT-CeA-vPAG neural pathway indicated by FOS staining in the CeA. **A1, A2**, The BDA-labeled axonal terminals (green) observed in the CeA coming from the pPVT. **B1, B2**, The FG-labeled neuronal somata and processes (blue) in the CeA retrogradely labeled from the vPAG. **C1, C2**, The FOS-labeled NeuNs (red). **D1, D2**, The FG/FOS double-labeled neurons surrounded by BDA-labeled fibers (white arrows in **D2**). The white square area in **D1** is enlarged and displayed in **A2–D2**. **A2–D2** show a projection of four optical sections and the total distance in the z-axis is 4.5 μm . Scale bars = 20 μm (**D1**; applied in **A1–C1**) and 10 μm (**D2**; applied in **A2–C2**).

Previous studies have shown detailed depiction of the brain regions innervated by PVT, which include the nucleus accumbens (NAc), BNST, and CeA (Moga et al., 1995; Li and Kirouac, 2008; Vertes and Hoover, 2008; Kirouac, 2015). Our anatomic results showed that the pPVT had dense connections with the CeL, which bore a high resemblance to that in previous neuroanatomical reports (Dong et al., 2017). Two retrograde tracers, i.e., FG and TMR, were used in our study to trace the pPVT-CeA pathway. Compared with TMR, FG has a better tracking effect, and FG-labeled neurons are more clearly defined. Therefore, we used FG as a tracer to observe the distribution of retrogradely labeled neurons in the pPVT after CeA injection. However, FG is sensitive to temperature changes, and the expression of FG decreases when the hybridization temperature is 50–60°C. Therefore, TMR was used for the FISH study. In addition, considering that FG's toxicity may affect the survival and activity of neurons during electrophysiological recording (Garrett et al., 1991), we also chose TMR as the retrograde tracer in this study (Carr et al., 1994).

The CeA receives nociceptive information from the PBN (Neugebauer and Li, 2003) and shows responses to noxious stimuli. Inhibiting amygdala activity with lesions or pharmacologic interventions decreases pain-related behaviors in different pain models (Pedersen et al., 2007; Fu and Neugebauer, 2008; Ren et al., 2013). In contrast, increasing amygdala activity can increase pain in normal rats (Han et al., 2010; Kolber et al., 2010). Previous reports have shown that long-term facilitation is only observed in the right amygdala in acute and inflammatory pain models (Carrasquillo and Gereau, 2007; Ji and Neugebauer, 2009). Neuropathic pain can cause sustained discharge enhancement in the right amygdala, but there is only transient activity enhancement in the left amygdala (Gonçalves and Dickenson, 2012). The mechanism involved in this left-right difference is not clear. The nociceptive information the SDH can be transmitted to the contralateral CeA through the PBN (Todd, 2010).

Therefore, in this study, the SNI operation was operated on the left side, and stereotactic injections and electrophysiology recordings in the CeA were performed on the right side.

In the present study, FOS staining showed that pPVT-CeA projection neurons were activated after SNI. In addition, an in vitro electrophysiology study also showed that the excitability of pPVT-CeA projection neurons was increased in neuropathic animals. Behaviorally, optogenetic activation of the pPVT projection fibers in the CeA induced hypersensitivity in naive rats. It has been reported that PVT neurons are mainly excitatory glutamatergic neurons (Hur and Zaborszky, 2005; Kirouac, 2015). In our study, we confirmed that the excitatory glutamatergic neurons in the pPVT that projected to the CeA were positive for VGLUT2 mRNA. It is well proven that the CeA contains medium-size spiny, GABAergic inhibitory neurons (McDonald, 1982; Cassell et al., 1986; Swanson and Petrovich, 1998; Fang et al., 2018). Collectively, our data suggest that the pPVT excitatory glutamatergic neurons send projections to the CeA GABAergic neurons and that the PVT-CeA pathway is involved in descending regulation of nociception.

The PAG plays a vital role in upstream and downstream nociceptive integration and transmission (Millan, 2002; François et al., 2017). The vPAG is regarded as the most effective portion that mediates stimulation and stress-induced analgesia (Millan, 2002) and is a key downstream target of CeA neurons (Tershner and Helmstetter, 2000). Dense connections between the CeA and vPAG were also observed in this study. Therefore, we confirmed the pPVT-CeA-vPAG pathway by neural pathway tracing combined with electron microscopy. The CeA neurons in the pPVT-CeA-vPAG pathway were activated by SNI, which indicated that the pPVT might trigger the endogenous descending facilitation of nociception through connectivity with CeA-vPAG projection neurons. Subsequently, we traced the pPVT^{Glu+}-CeA-vPAG^{Glu+} pathway between the CeA projection neurons and the glutamatergic neurons of the vPAG, which showed that

Figure 12. Fluorescent photomicrographs observation of the pPVT-CeA-vIPAG pathway. **A, B**, Schematic diagrams of the experimental procedure, the constructs and sequences of the adeno-associated viruses (AAV2/9-Ef1α-DIO-EYFP) and the rabies-based viruses. **C**, The virus injection sites in the pPVT (green, **C1**) and the vIPAG (yellow, **C2**). **C2**, VGLUT2 starter cells are labeled in yellow, and presynaptic partners throughout the brain are labeled in red. 3v: the third ventricle; Aq: aqueduct; dm: dorsomedial subregion of the PAG; dl: dorsolateral subregion of the PAG; l: lateral subregion of the PAG; vl: ventrolateral subregion of the PAG; DR: dorsal raphe nucleus. Scale bar = 200 μm (**C2**; applied in **C1**). **D1–D3**, The pPVT projecting glutamatergic terminals in the CeA (green). **E1–E3**, The dsred-labeled presynaptic projection neurons in the CeA. **F1–F3**, The connections (white arrows in **F3**) between the pPVT projecting glutamatergic terminals and the CeA-vIPAG projection neurons. The white square area in **F2** is enlarged and displayed in **D3–F3**. **C–F** are coming from the same mouse. Scale bars = 100 μm (**F1**; applied in **D1, E1**), 10 μm (**F2**; applied in **D2, E2**), and 5 μm (**F3**; applied in **D3, E3**).

the VGLUT2⁺ vIPAG neurons were the target of the pPVT-CeA pathway. Glutamatergic vIPAG neurons with a marked analgesic effect have been verified (Tovote et al., 2016). Our results concluded that VGLUT2 glutamatergic neurons in the pPVT and vIPAG in the pPVT-CeA-vIPAG pathway play an important role in nociceptive descending facilitation. In the present study, rats were the main research subject. However, the VGLUT2-ires-Cre transgenic mice were used to identify the types of pPVT and vIPAG neurons on the pPVT-CeA-vIPAG pathway. The existences of the pPVT-CeA and CeA-vIPAG pathways have been reported in these two species (Rizvi et al., 1991; Li and Kirouac, 2008; Do-Monte et al., 2015). Moreover, based on our neuronal tract tracing results of Figures 10 (rats) and 12 (mice), the similar fiber connections on the pPVT-CeA-vIPAG pathway are found in the brains of rats and mice.

Recently, the PVT has received more attention about its involvement in fear, feeding, and controlling wakefulness. The present study further highlights the pPVT as a key nucleus that mediates nociceptive information modulation and the circuit from pPVT to CeA to PAG decreases descending inhibition of pain. Inactivation of this circuit might be a direct and useful therapeutic method to alleviate chronic pain. However, further studies are necessary to elucidate the different roles and interactions of distinct types of neurons in this pathway involved in pain modulation.
